Profuse watery diarrhea with poor weight gain and/or weight loss is a common syndrome seen in ruminants with copper deficiency.[1086] When it occurs in animals on boggy pastures that contain high concentrations of molybdenum, it has been referred to as *teart*.[1086] Decreased weight gain or weight loss as a herd problem can have many other causes, including parasitism, trace mineral deficiencies (selenium, cobalt), protein calorie malnutrition, and Johne's disease. A syndrome characterized by epiphyseal enlargement, stiffness, and unthriftiness is seen in young ruminants as a result of copper deficiency[1087] and is sometimes called *pine*.[1086] Copper deficiency can cause spontaneous fractures in ruminants. Enzootic neonatal ataxia (swayback) of lambs and kids is characterized by progressive incoordination and recumbency that begins with the hindlimbs and progresses to the forelimbs. It has also been reported in deer and pigs. Inadequate keratinization of wool and achromotrichia are the result of imperfect oxidation of free thiol groups during hair growth and keratinization. Subsequently the wool fibers do not crimp normally, and they appear to be “stringy” or “kinky.” A copper-containing enzyme, tyrosinase (polyphenyloxidase), is needed to convert L-tyrosine to melanin. With copper deficiency, this conversion is slow and hair is lighter in color than normal (achromotrichia). Loss of wool crimp and pigmentation changes in sheep or cattle, respectively, occur late in the course of copper deficiency. In addition to the described clinical syndromes, which may occur alone or jointly, copper deficiency may be associated with anemia[1088] (altered iron metabolism) or infertility.[1089] Infertility is probably multifactorial and may not respond to an increase in copper intake alone. Copper deficiency also seems to result in decreased immune function in ruminants.[1090,1091]

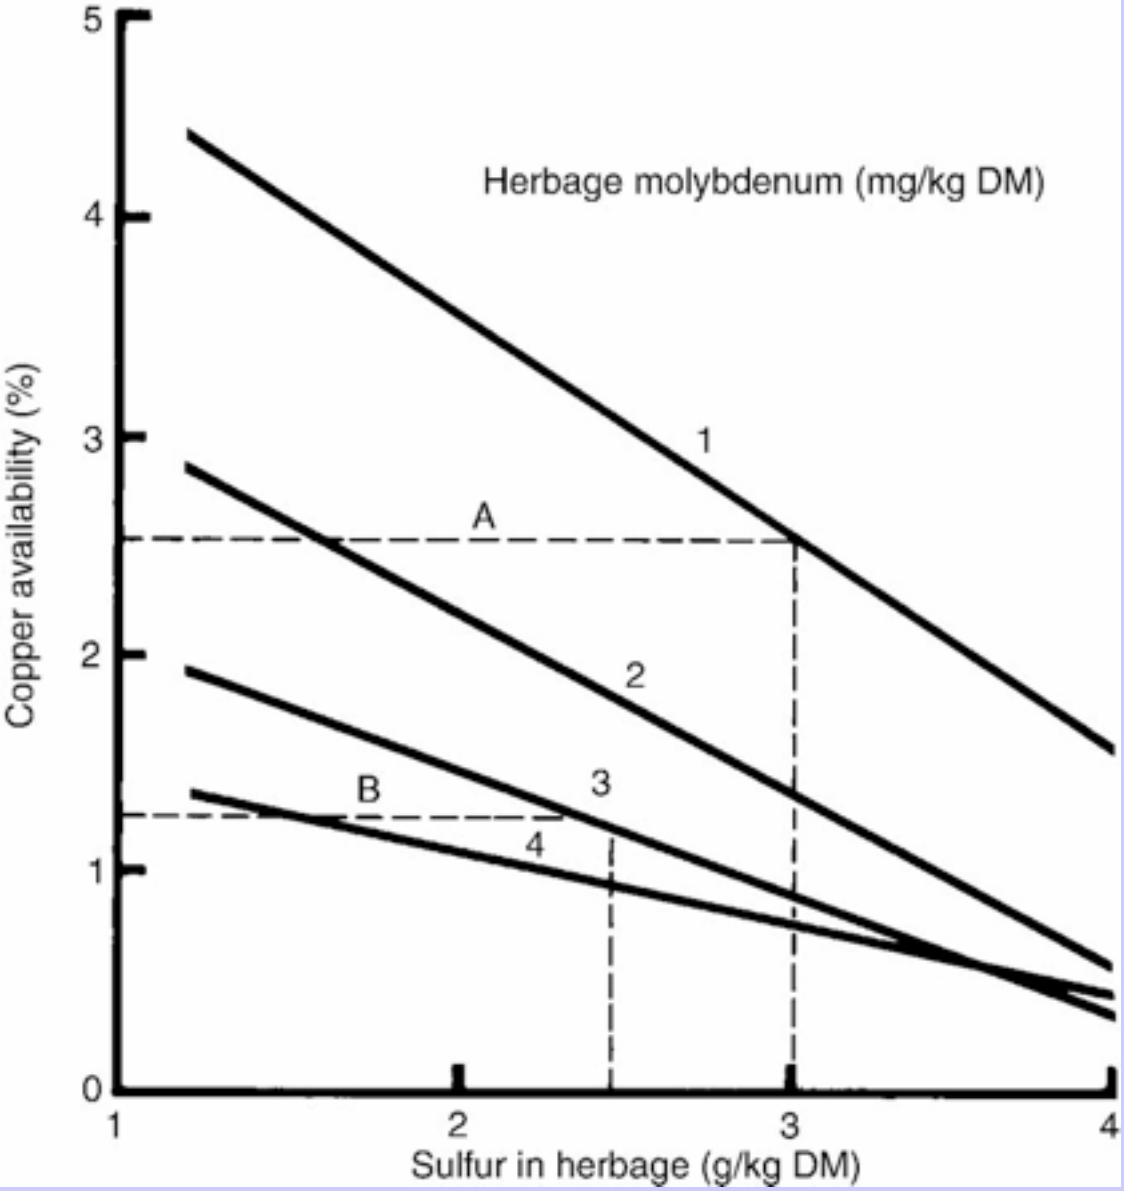
887 888

32.159.3 Pathogenesis

A frank dietary deficiency of copper results in hypocuprosis and eventual clinical signs. Also, a variety of conditions can decrease copper absorption from the gastrointestinal tract (large intestine in sheep and small intestine in cattle). The interactions among dietary copper, molybdenum, and sulfates (or sulfur) are important (Fig. 32-106). Excess dietary molybdenum can lead to the formation of sparingly soluble cupric molybdates in the rumen that are not absorbed from the intestine. The addition of excess sulfur or sulfates in the diet and/or water can result in the formation of insoluble copper thiomolybdates in the rumen. The interactions among these three elements are complex.[1092] The infertility seen with secondary copper deficiency may be a result of excess circulating oxythiomolybdates, which interfere with the release of luteinizing hormone.[1093] It is important to note that at low sulfur concentrations in the diet excess molybdenum has a minimum effect on decreasing copper absorption. Even when no dietary molybdenum or sulfates are present, only about 5% of ingested copper is normally absorbed. Excessive calcium in the diet, particularly in the form of limestone, decreases copper absorption. Excessive iron, 30 mg/kg of body weight or 1200 ppm in the diet of calves, reduces copper absorption.[1094] Overgrazing, with the subsequent ingestion of excess soil, also decreases copper absorption. In addition, excess cadmium (3 to 7 ppm) or excess zinc (100 to 400 ppm) reduces hepatic copper concentration, probably through the combined effects of decreased absorption and competition with copper for hepatic metallothionein.[1095,1096] It had been suggested that excess dietary selenium might interfere with copper absorption and/or usage; recently this was shown not to be the case.[1097] Copper is an essential component of a number of mammalian enzymes. Some of the medically important copper-containing enzymes are (1) the cytosol form of superoxide dismutase (copper and zinc), (2) cytochrome oxidase (c and aa_3), (3) lysyl oxidase, (4) ascorbic acid oxidase, and (5) ceruloplasmin.[1098] In addition, normal copper nutrition appears essential for iron absorption and transportation of iron to the liver and reticuloendothelial system and is therefore necessary for normal hemoglobin formation. The precise pathophysiology of most of the copper deficiency syndromes is not known. However, the central role of copper in preventing cellular oxidative damage and its role in iron and sulfur metabolism are probably important.

Fig. 32-106 Estimating the availability of copper in herbage from its

molybdenum and sulfur concentration. The difference of 3 mg of molybdenum and 0.5 g of sulfur per kilogram of dry matter between pastures A and B is sufficient to reduce availability from 2.6% to 1.3%, doubling the grazing animal's requirement of copper from the pasture. From Suttle NF: Copper deficiency in ruminants; recent developments, *Vet Rec* 119:519, 1986.



32.159.4 Epidemiology

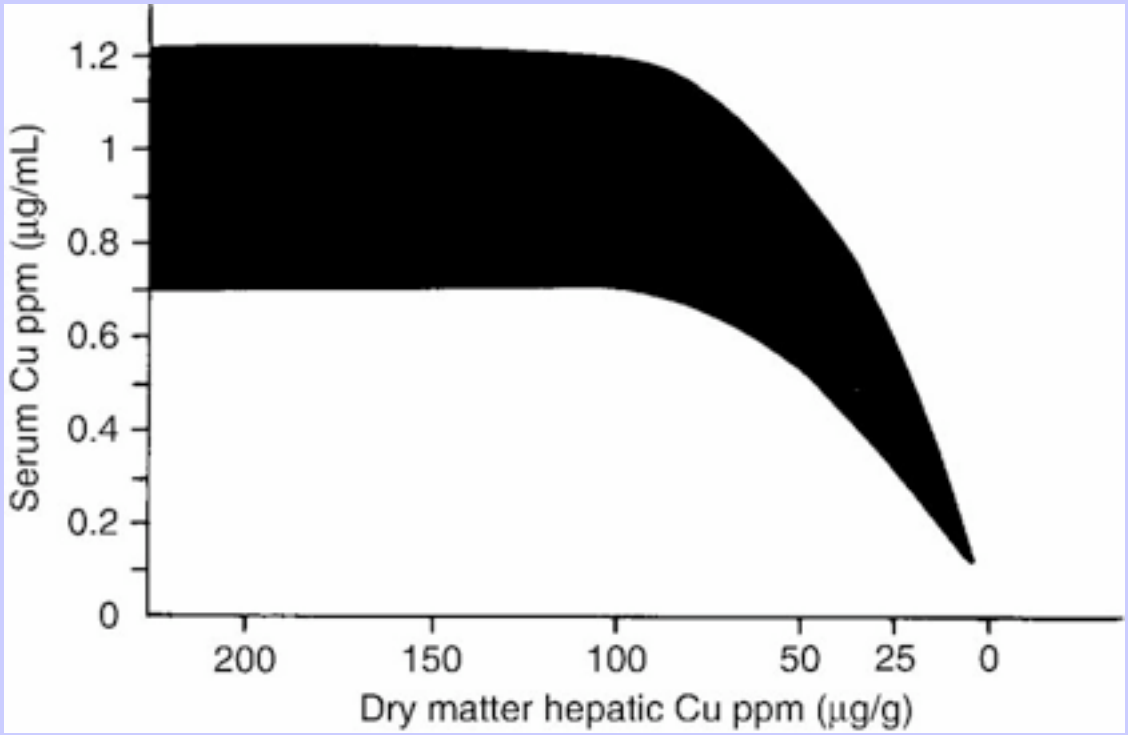
Copper deficiency can occur when diets are inadequate in copper or contain excess amounts of interfering substances, particularly sulfates and molybdenum. This occurs in many parts of North America. Forages and water can be sources of molybdenum, sulfur, and sulfate. To avoid primary copper deficiency, pasture (dry matter) should contain over 5 ppm of copper, with 3 to 5 ppm considered marginal, and less than 3 ppm deficient. Soil copper concentrations are generally slightly lower than those of the harvested forage. Molybdenum adversely affects plant uptake of copper. Forage molybdenum concentrations greater than the copper concentrations often lead to secondary copper deficiency, even when forage copper is adequate. Because copper content in grasses and legumes can be different, forage samples must be randomly selected to reflect dietary intake. Forage copper concentrations as high as 12 to 27 ppm have been associated with copper deficiency when molybdenum levels are high.[1086] The critical ratio of copper to molybdenum in feeds is 2:1, with 5:1 recommended for sheep and 5:1 to 10:1 for grazing cattle.

32.159.5 Clinical Pathology and Diagnosis

The primary site of copper reserves is the liver, and the copper concentration in the hepatic tissue is the best indicator of copper status (Fig. 32-107). The reference range for hepatic copper concentrations in cattle is approximately 90 to 200µg/g (ppm) and in sheep 90 to 250µg/g on a dry weight basis (DMB).[1086,1099,1100] Hepatic copper concentrations as high as 250µg/g DMB are not unusual in supplemented ruminants (even over 350µg/g DMB in sheep). Blood copper concentrations can be maintained near normal until hepatic copper concentration falls to 35ppm DMB or less, at which time the serum copper concentration invariably begins to decrease.[1101] When using blood samples for copper determination, serum or plasma is normally preferred. Plasma copper concentration is usually about 5% greater than an identical serum copper concentration.[1102] Normal serum copper is 0.7 to 1.2ppm (µg/mL).[1086,1098] Serum or plasma copper concentrations of 0.4ppm or less are considered evidence of frank deficiency. Values of 0.4 to 0.7ppm are marginal, and it is difficult to estimate the actual liver copper concentration. Approximately 50% to 90% of the copper in serum or plasma is present in ceruloplasmin. The remainder is bound to albumin or amino acids. The correlation between serum copper and serum ceruloplasmin was found to be weak (0.50)[1102]; therefore ceruloplasmin is not commonly used to aid in diagnosing copper deficiency. Hepatic copper concentration is the preferred diagnostic sample and is easily secured at necropsy. Hepatic copper values less than 35ppm DMB are considered deficient.[1086,1099–1101] However, surgical biopsy is necessary for live patients, and because laboratories generally require 100mg or more of tissue, a biopsy instrument with an internal diameter of 3 to 5mm is necessary.[1103] The biopsy procedure in cattle is performed by locating the tenth intercostal space on the right side of the animal along a line from the tuber coxae (point of the hip) to the point of the shoulder.[1103] This site is surgically prepared and blocked with lidocaine (12mL of 2% lidocaine), and a stab incision is made. The biopsy instrument is directed slightly ventrad and craniad and advanced through the intercostal space and the diaphragm to enter the liver, where the biopsy sample is obtained.[1103] The liver biopsy can place the patient at increased risk for black disease or bacillary hemoglobinuria in some areas of the United States. This risk should be decreased by prior vaccination and a single dose of procaine penicillin G (4 million I.U. SC) administered at the time of the biopsy.[1103] This technique has been shown to be safe and effective.[1103] The tissues of young animals (neonates) contain variable amounts of copper compared with adults of the same species. In sheep, serum and liver copper concentrations are the same for lambs (1 week of age) and adults.[1104] The plasma copper levels in lambs are low at birth but rise to adult values by 1 to 7 days of age. Plasma copper levels in the bovine neonate are lower than in mature cattle.[1105] In the bovine neonate hepatic copper concentration changes little from birth to maturity; however, copper distribution in the liver is quite variable in the neonate.[1100,1105] Because of these differences, interpretation of

distribution in the liver is quite variable in the neonate.[1105] Because of these differences, interpretation of neonatal serum copper concentrations is difficult. Milk is a poor source of copper, containing only 0.2 to 0.6ppm in normal ewes and 0.01 to 0.02ppm in severely copper-deficient ewes or cows. Milk copper in cattle is 0.05 to 0.2ppm. To make matters worse, molybdenum is concentrated in milk.[1106]

Fig. 32-107 Relationship between the serum and hepatic copper concentrations in ruminants.



32.159.6

Treatment and Control

Treatment of copper-deficient animals is usually possible, and the prognosis is guarded to good, depending on the severity of the deficiency and the associated syndrome(s). When excess molybdenum, sulfate, and other factors leading to secondary deficiency are present, they can be overcome to some extent by increasing dietary copper or by injecting copper glycinate. Copper glycinate must be prescribed by the attending veterinarian and dispensed by a compounding pharmacy because no commercial over-the-counter products are currently available. Injectable copper glycinate (30% copper by weight) is given to adult cattle at the rate of 400mg (120mg of copper) SC. Calves are given 100 to 200mg of copper glycinate (30 to 60mg of copper), depending on their age. One injection may be effective as a treatment or supplement for up to 4 to 6 months in cases of primary copper deficiency. However, in cases of excess molybdenum, sulfates, and/or sulfur, repeat injections may be necessary. Injections of copper glycinate frequently result in large swellings, granulomas, or abscesses and may be cosmetic considerations for some cattle. The reactions can be minimized by using sterile technique and using the subcutaneous tissue of the brisket as the injection site. Acute deaths can occur in calves after the use of copper glycinate injections. In some countries copper disodium edetate (copper EDTA) solutions are used as injectable copper supplements. The dose of copper is usually the same as that recommended for copper glycinate

solutions. However, acute deaths can also occur after use in cattle.[1107] Copper can be supplemented to cattle in salt-mineral mixes in situations in which adequate consumption (1 to 2oz [28 to 56g]/cow/day) of the salt-mineral mix occurs. These mixes are usually 0.2% to 0.6% copper. Feed-grade copper sulfate ($CuSO_4$-5 H_2O) is 25% copper on an as-fed basis (40% copper DMB). Feed-grade copper oxide is usually 50% copper as fed (80% copper on 100% DMB). To make a 0.4% copper salt mixture, add 7.2g of $CuSO_4$ or 3.6g of CuO to each 454g (1lb) of salt. For large batches add 32 ob of $CuSO_4$ or 16lb of CuO per ton of salt. Salt mixtures for copper-deficient sheep should usually contain only 0.0625% to 0.13% copper (0.25% to 0.5% copper sulfate). Copper supplements can be added to a TMR easily in the form of trace mineral—vitamin premixes or premix-containing pellets. Copper sulfate can be added to molasses or other sweet feed at 0.363g/head/day for mature cattle and correspondingly less for calves. This would supply approximately 91mg of copper to a 450-kg (1000-lb) cow per day or 10ppm of the total diet (20lb [9.1kg] of dry matter). The copper in $CuSO_4$ is more available than that in CuO. Another method of copper supplementation involves the oral administration of copper oxide needles (fine rods, 1 to 10mm long) placed in gelatin capsules, which dissolve in the reticulorumen and liberate the CuO wires. These wires reside in the reticulum and abomasum and slowly release copper for absorption. These boluses are currently available in the United States (Copasure) and contain either 25g or 12.5g per bolus. The usual recommended dose is 25g per animal 500lb or heavier. One 12.5-g bolus is recommended for calves, and the usual dose is 2 to 4g for ewes and does,[1086,1108,1109] which is an extralabel recommendation for sheep and goats. The copper oxide needles are thought to provide copper supplementation for 4 to 12 months. Sheep are particularly susceptible to copper toxicity, and appropriate care is necessary when supplementing them. Sheep can easily be intoxicated when consuming cattle supplements or feeds. Continued monitoring of hepatic copper concentration from slaughtered animals or via liver biopsy is an important tool in evaluating copper supplementation methods in cattle and sheep. Lambs can be given 35mg of copper sulfate per head twice weekly to prevent swayback in endemic areas. The usual recommendation by the National Research Council is 10ppm (10mg/kg) of the total diet DMB for cattle. However, diets of 20ppm are commonly fed to lactating dairy cattle. The most important goal of copper supplementation is to provide adequate dietary amounts without oversupplementing or risking toxicity.

32.160 COBALT DEFICIENCY IN RUMINANTS

John Maas

32.160.1 Definition and Etiology

A number of syndromes occur in ruminants as a result of a primary cobalt (Co) deficiency in their diet. These include ill thrift or enzootic marasmus and anemia. These conditions are characterized by decreased growth, weight loss, diarrhea, decreased feed efficiency, unthrifty appearance, anorexia, and anemia. Recently, a Co deficiency syndrome referred to as *ovine white liver disease* has been described in sheep.[1110–1112] This syndrome is also characterized by ill thrift, weight loss, serous ocular discharge, and occasionally photosensitization.[1110–1112] Histopathologic lesions of this syndrome included accumulation of lipid droplets and lipofuchsin particles, dissociation and necrosis of hepatocytes, and sparse infiltration by neutrophils, macrophages, and lymphocytes.[1112]

889
890

32.160.2 Clinical Signs and Differential Diagnosis

Co deficiency in ruminants is associated with the nonspecific signs of decreased growth, weight loss, diarrhea, ill thrift, pica, emaciation, pale mucous membranes (anemia), and lacrimation. Clinical disease is more common in young, growing animals. Sheep are apparently more susceptible to Co deficiency than cattle. Primary differential diagnoses include helminthic parasitism; protein-calorie malnutrition; coccidiosis; Johne's disease; nutritional deficiencies of selenium, copper, or vitamin D; and other causes of chronic disease that may be associated with weight loss.

Co-deficient ruminants are commonly anorectic and fail to thrive on lush pasture or high-quality feeds. Anemia with cobalt deficiency is characterized as normocytic normochromic and must be differentiated from other causes of anemia. Co-deficient cattle are more susceptible to infestation with *Ostertagia ostertagi* and to the effects of parasitism.[1113] The primary differential diagnosis when considering Co deficiency is invariably internal parasitism.

32.160.3 Clinical Pathology and Diagnosis

Because the role of Co in ruminant nutrition is tied to the formation, absorption, and use of vitamin B_{12}, the most significant clinical chemistry analysis is tissue vitamin B_{12} concentration. However, the effects of starvation tend to increase vitamin B_{12} concentrations in liver and kidney.[1114] If Co deficiency occurs with other conditions that cause anorexia, the tissue vitamin B_{12} concentrations may appear falsely normal. Criteria used for sheep[1115] (and by extrapolation for cattle) are found in Table 32-24.

Serum vitamin B_{12} analysis is advantageous in many clinical settings. Serum or plasma vitamin B_{12} levels exhibit a marked diurnal variation.[1116] Serum vitamin B_{12} concentration more closely reflects short-term Co intake and can be decreased when adequate liver reserves of vitamin B_{12} remain. In normal, Co-sufficient ruminants, serum vitamin B_{12} values are usually 1 to 3ng/mL. When serum vitamin B_{12} values decrease to 0.3ng/mL, the threshold for clinical signs has been reached; when serum vitamin B_{12} values of 0.2ng/mL or less are reached, marked signs of Co deficiency are evident.[1117]

Severe Co deficiency in ruminants results in the excretion of methylmalonic acid (MMA) and formiminoglutamic acid (FIGLU) in the urine.[1118] Urinary FIGLU levels of 0.08 to 0.2µmol/mL would be presumptive evidence of Co deficiency, and the urinary FIGLU level should return to zero after vitamin B_{12} administration. Use of urinary MMA for diagnosis is best accomplished by loading the rumen with propionate and then comparing the urinary excretion of MMA with and without vitamin B_{12} supplementation. The fact that urinary MMA and FIGLU excretion occur very late in the course of Co deficiency limits the routine use of these methods for diagnosis.

Table 32-24 Criteria Used to Determine Cobalt Deficiency in Sheep

Condition of Animal (Co or B_{12} status)	Concentration of Vitamin B_{12} (mcg/g of Fresh Liver)[1115]
Severe cobalt deficiency	<0.07
Moderate cobalt deficiency	0.07–0.10
Mild cobalt deficiency	0.11–0.19
Cobalt sufficiency	0.19

32.160.4 Pathophysiology

Co deficiency in ruminants induces a deficiency of vitamin B_{12} (cyanocobalamin). It is the lack of vitamin B_{12} that is thought to cause the majority of clinical signs and clinicopathologic abnormalities observed. Monogastric species need to ingest vitamin B_{12} preformed, whereas ruminants can manufacture adequate vitamin B_{12} if the ruminal microorganisms are supplied with adequate Co in the diet. The ruminal microorganisms incorporate Co into vitamin B_{12} and a number of physiologically inactive vitamin B_{12}-like compounds. The production of vitamin B_{12} from dietary Co was estimated in one study to be about 15% in Co-deficient sheep and only about 3% in Co-sufficient sheep.[1119] About 50% of the vitamin B_{12} produced is absorbed in normal animals, but only 3% to 5% of vitamin B_{12} is estimated to be absorbed by Co-deficient sheep.[1120] Although the absorption of vitamin B_{12} formed in the rumen is not particularly efficient, with normal dietary Co there are usually no clinical problems, and interference by other dietary components does not appear to be important.

Ruminants use the VFAs acetate, propionate, and butyrate as their primary energy source. Propionate produced in the rumen is the precursor of glucose for ruminant metabolism. The general metabolic steps for conversion of propionate to glucose are shown[1121] (Fig. 32-108).

A primary defect in Co-deficient ruminants is the inefficient metabolism of propionate at the point in the pathway at which methylmalonyl-CoA mutase, a vitamin B_{12}-requiring enzyme, catalyzes the conversion of methylmalonyl-CoA to succinyl-CoA.[1122] As Co deficiency becomes severe, the rate of propionate clearance from the blood decreases, and the intermediate metabolite methylmalonyl-CoA accumulates.[1123] With severe Co deficiency, the amount of MMA excreted in the urine increases.[1118] As the half-time for propionate clearance increases, the voluntary feed intake of Co-deficient sheep decreases.[1123] These changes correlate with the degree of anorexia and weight loss observed in severely Co-deficient sheep.

The decreased growth, weight loss, unthrifty appearance, and anorexia are closely correlated to the observed abnormalities of carbohydrate metabolism. The diarrhea commonly observed with Co deficiency is not well explained; however, an increase in susceptibility to parasitism[1110] might explain a portion of this clinical observation.

The anemia that is associated with Co deficiency occurs late in the development of the syndrome and is characterized as normocytic normochromic.[1124] Cobalt deficiency results in the depression of the vitamin B_{12}-containing enzyme 5-methyltetrahydrofolate homocysteine methyltransferase.[1125] This interference with the recycling of methionine has a marked influence on folate metabolism. In addition to potentially resulting in anemia through inefficient folate metabolism, the decreased activity of this methyltransferase could lead to a

deficiency of methionine; this is a possible reason for nitrogen retention and decreased body growth and wool growth observed.

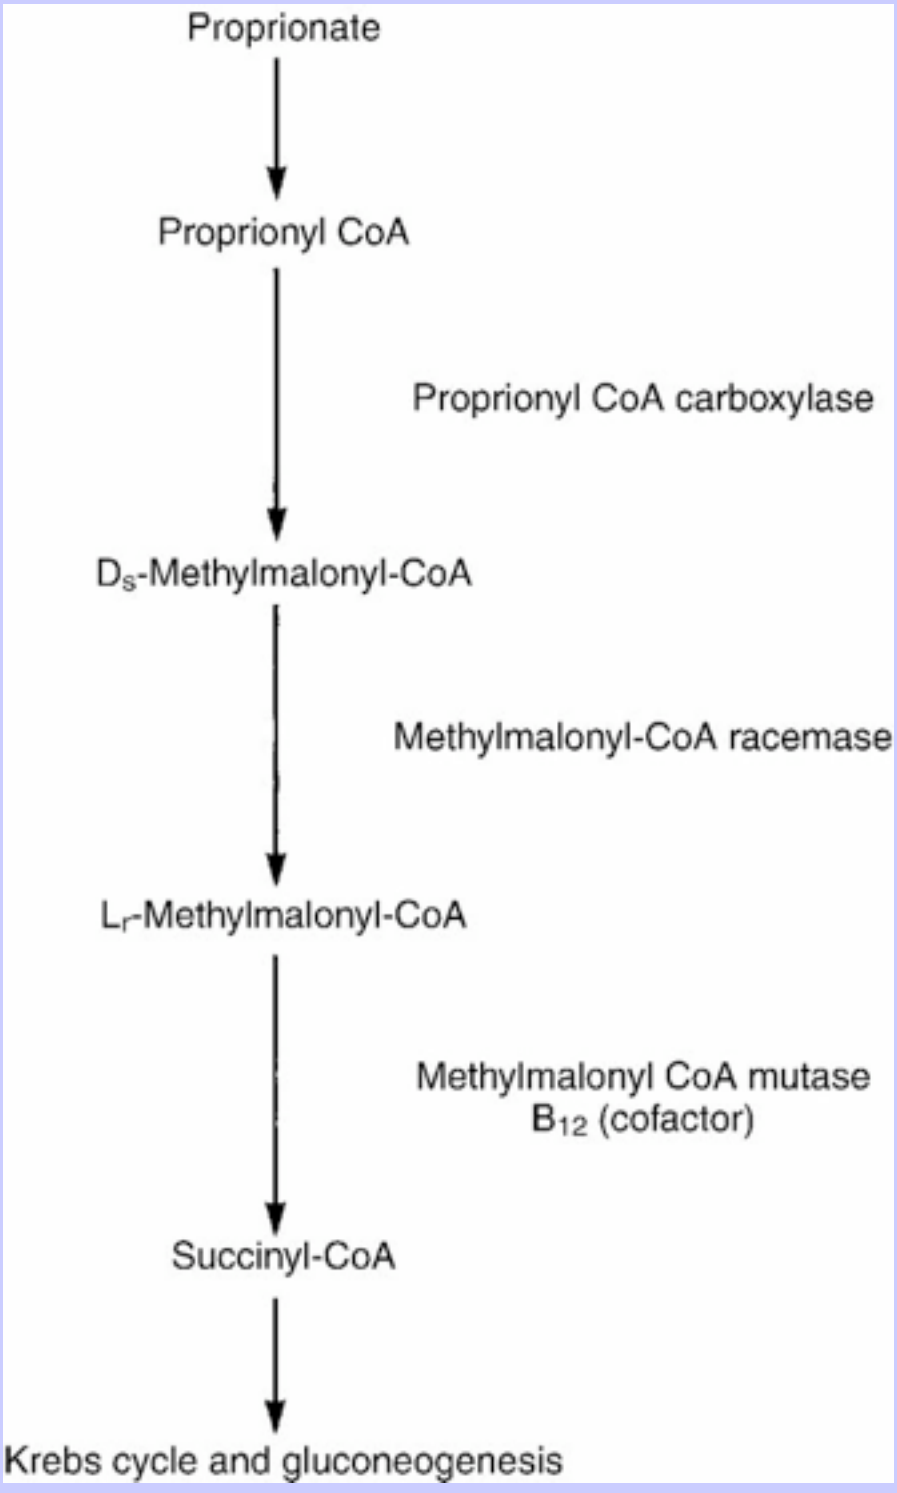
32.160.5 Epidemiology

890
891

Co deficiency in ruminants occurs in selected regions throughout the world and in association with a variety of soil types. Clinically recognizable Co deficiency is reported in New Zealand, Australia, Brazil, the United Kingdom, Ireland, Scandinavia, and North America. In the United States, Co deficiency is most commonly seen in Florida, in the Northeast, along the eastern seaboard, in the upper Midwest, and around the Great Lakes.[1126] Although various soil types are associated with Co deficiency, heavy fertilization with limestone reduces the Co available to plants and animals.[1127]

Fig. 32-108 Pathway for conversion of propionyl CoA (from propionate) to

succinyl CoA.



The dietary intake of Co by ruminants is generally recommended to be 0.1mg/kg of dry matter (DM) of the

complete ration.[1128–1130] The Co requirement of young, rapidly growing lambs is thought to be 0.2mg/kg of DM of the diet.[1131] When pasture Co concentrations are less than 0.07mg/kg of DM or 0.04mg/kg of DM for sheep and cattle, respectively, signs of deficiency can be expected to develop. On a practical basis, diets with 0.1mg/kg of DM are considered to be adequate. Legumes have relatively high Co concentrations. Rapidly growing grasses have much lower Co concentrations, and cereal grains are poor sources of Co.[1128] Oilseed meals are generally good sources of Co.

32.160.6 Treatment and Control

Treatment is best accomplished in the short term with vitamin B_{12} injections. Ruminants poorly absorb oral vitamin B_{12}; therefore injections are more efficient. Lambs receiving 100µg of vitamin B_{12} per week or 150µg of B_{12} every other week show remission of clinical signs.[1132] Sheep receiving injections of 300µg of vitamin B_{12} weekly or cattle receiving 2000 to 3000µg of vitamin B_{12} weekly would also be expected to regain normal status.

Rations with 0.1 to 0.2mg of DM Co per kilogram (ppm) would be expected to prevent Co deficiency in ruminants. Salt-mineral mixes containing 0.1% Co also provide adequate supplementation. 0.1% Co in salt can be made by mixing cobalt carbonate (which is 46% cobalt) at the rate of 4.35lb/ton of salt, or 1g of cobalt carbonate per pound of salt.

Cobalt sulfate as a top dressing for pastures (1.5kg/hectare every 3 to 4 years or 0.3kg/hectare every 1 to 2 years) has been used to increase Co concentration of pasture forage. Heavily limed pastures[1127] and soils high in manganese oxide[1133] decrease Co availability, and Co top dressing of the pastures or Co (B_{12}) supplementation to the animals should be considered.

A variety of ruminal pellets containing Co are used to supplement grazing ruminants. These pellets have been successful in maintaining normal Co status in animals.[1131–1134] The pellets are not commercially available in the United States at this time.

The perennial grass, *Phalaris tuberosa*, can cause a syndrome in ruminants that is referred to as “phalaris staggers.” Co supplementation can aid in prevention of this syndrome because it inactivates or decreases absorption of the neurotoxin contained in *P. tuberosa, Phalaris minor* (canary grass), or *Phalaris* hybrids (ronpha).[1135] The increased level of Co in the rumen is the important factor in preventing this condition; administration of oral or parenteral vitamin B_{12} is not effective.[1135] Treatment of clinical phalaris staggers with Co is not effective, however.

Because Co is poorly absorbed, toxicity is an uncommon problem, and diets in excess of 30mg/kg of DM are necessary for toxicosis to occur in most cases.[1128–1130]

32.161 RECTAL PROLAPSE IN RUMINANTS AND HORSES

Spring K. Halland

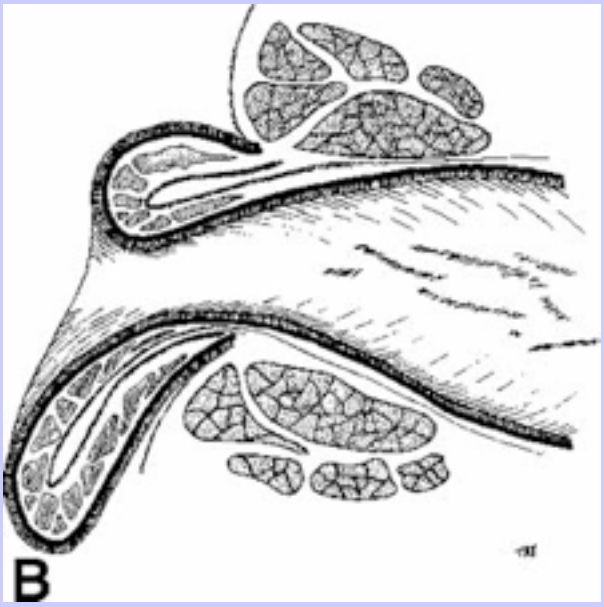
32.161.1 Definition and Etiology

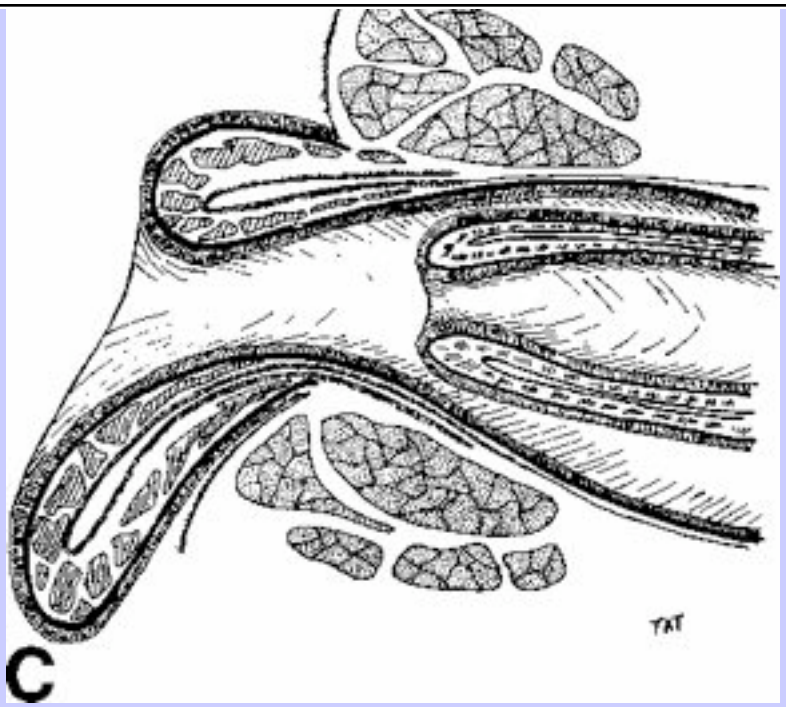
Rectal prolapse is the protrusion of the rectal mucous membranes through the anus. This evagination may be extensive and may include part of the small colon. Rectal prolapse occurs in all domestic animals, with the highest incidence in cattle, sheep, and swine. The age at which prolapse most commonly occurs is 6 to 12 months in sheep, 6 months to 2 years in cattle, and 6 to 12 weeks in swine.[1136] Rectal prolapse is much less common in horses and occurs more often in mares than in males.[1137]

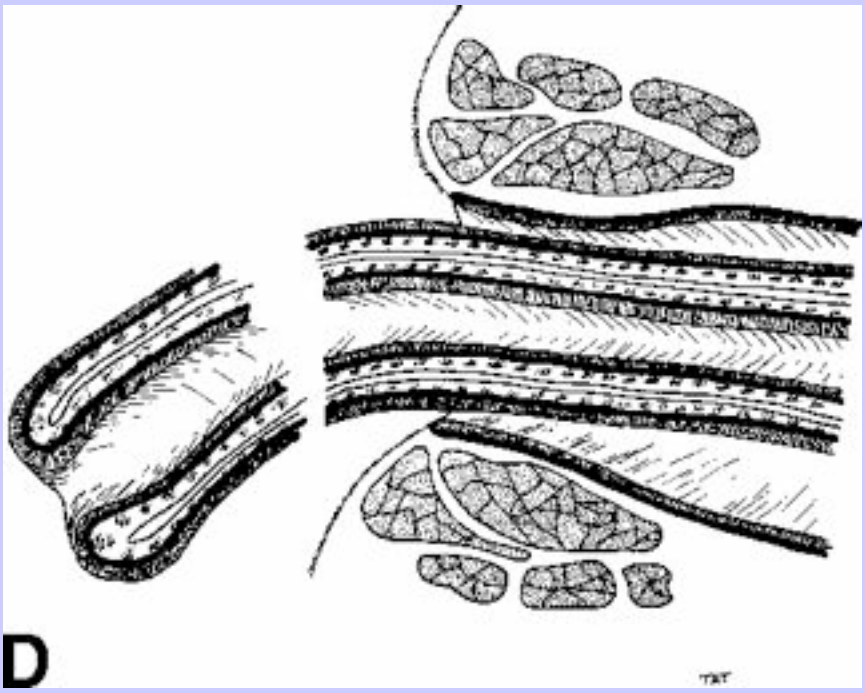
Rectal prolapse generally is the result of an increase in the pressure gradient between the abdominal or pelvic cavity and the anus. Factors that cause the increased pressure gradient can be divided into four categories: (1) factors that result in increased abdominal fill (e.g., excess fat, bloat, and large or multiple fetuses); (2) factors that cause tenesmus (e.g., enteritis, colitis, intestinal parasitism [coccidiosis], liver disease, constipation, proctitis, urinary obstruction, dystocia, aftermath of rectal examination, and false copulation); (3) conditions that result in chronic or excessive coughing (e.g., pneumonia, parasitism, and adverse environmental conditions); and (4) miscellaneous conditions (e.g., use of growth implants, space-occupying lesions, congenital or acquired sphincter tone problems, and short tail docking [especially noted in sheep]). One study strongly revealed that sheep with short docked tails (as close to the body as possible) had a 7.8% higher incidence of rectal prolapse when finished on a high concentrate diet.[1138] Certain toxicities such as from lead, fluoride, estrogen, and zinc have been implicated as playing a role in rectal prolapse.[1139] Any combination of factors may precipitate a rectal prolapse. Identification of predisposing factors becomes important in management of the case.

Fig. 32-109 **A**, Type I rectal prolapse. Mucosal prolapse, involving only mucosa

and submucosa of the rectum. **B**, Type II rectal prolapse. Complete prolapse, involving full wall thickness of the rectum. **C**, Type III rectal prolapse. Complete prolapse plus intussusception of peritoneal rectum or small colon. **D**, Type IV rectal prolapse. Intussusception of the peritoneal rectum or small colon or both. From Robinson NE, ed: *Current therapy in equine medicine*, ed 2, Philadelphia, 1987, Saunders.







891

892

32.161.2 Clinical Signs

Four categories have been used to described rectal prolapse: type I, mucosal prolapse; type II, complete prolapse; type III, complete prolapse with invagination of the colon; and type IV, intussusception of the peritoneal rectum or colon through the anus (Fig. 32-109).[1140] Types I and II are much more common and more amenable to correction. On physical examination, types I, II, and III are continuous with the mucocutaneous junction of the anus, whereas with type IV a protrusion with a palpable trench inside the rectum is seen.[1140] Chronic cases can be seen and usually are type I or II. Types III and IV often cause loss of vascular integrity to the rectum or small colon and require more immediate intervention. Types III and IV may accompany dystocias in mares.[1141]

32.161.3 Treatment and Prognosis

The first aim of therapy is identification and alleviation of the cause if possible. Early identification and correction of the prolapse is essential to saving tissues and the animal. The animal's value and intended use and the affected tissue's viability need to be considered when deciding on conservative or surgical options. The color of the membranes is a good parameter for determining if the tissue is salvageable. In general, the rectum is a forgiving structure, and attempts should be made to salvage the prolapsed tissue unless it is obviously cyanotic, necrosed, and devitalized.[1136] To prevent further damage, animals should remain standing and restrained in a small area until the prolapse can be corrected.

Types I and II usually are treated conservatively. A caudal epidural is necessary to reduce straining and facilitate correction of the prolapse. Sedation may also be necessary, depending on the individual animal. Effective conservative therapy includes thorough cleansing of the prolapse with warm water and mild soap to remove all debris. This allows evaluation for trauma, tears, necrosis, or sloughing. Edema can be removed by gentle kneading combined with topical application of glycerin or sugar. Generous lubrication and massage allow for reduction of the mass into the rectum. To ensure that the rectum is maintained in place, purse-string sutures using umbilical tape or other nonabsorbable suture are placed circumferentially around the anal sphincter, with care taken not to enter the rectum. The purse-string should not be so tight as to prohibit the passage of feces. If necessary, it should be loosened daily to expedite removal of accumulated fecal material. The purse-string should be removed in 3 to 4 days. In addition to purse-string sutures, counterirritants such as Lugol's iodine are often used.[1136] Two to 3mL of these irritants are injected with a 7.5-cm needle at the 4, 8, and 12 o'clock positions around the rectum. The counterirritants create an inflammatory response that results in scar formation, which retains the prolapsed tissue after the purse-string has been removed. Broad-spectrum antimicrobial drugs should be administered if tissue compromise is a factor. When indicated, stool softeners and enemas may be used to ease the passage of feces through the rectum.

Surgical intervention often is necessary if type I or type II prolapse cannot be reduced, if tissue necrosis is extensive, or if prolapse recurs after conservative therapy.[1140] Submucosal resection, amputation, or the use of a prolapse ring are all accepted surgical options. Prolapses of types III and IV that cannot be manually reduced often require a celiotomy for surgical reduction of the intussusception or resection or both. An important fact to remember is that even with manual reduction of a type IV prolapse, significant vascular compromise may have occurred, resulting in bowel leakage and peritonitis. Vascular damage encountered by the colon may necessitate a colostomy.[1486] Broad-spectrum antimicrobial drugs should be administered in these cases.

Unique problems are encountered when conservatively managing equine rectal prolapse versus ruminant

prolapse. Equine patients may experience more hindlimb ataxia with caudal epidurals, which can be prevented by using different combinations of xylazine, lidocaine, detomidine, morphine, and/or mepivacaine in the epidural. Placement of an epidural catheter can facilitate long-term therapy if needed.[1142] Another problem encountered is that horse feces often are too large and dry to readily pass through the purse-string in the anus. The use of enemas and stool softeners offers some assistance. The sutures tend to cause greater anal irritation than is seen in ruminants, causing the horse to strain against them.

The common complications after rectal prolapse include prolapse recurrence, rectal strictures, obstipation, formation of a pararectal abscess, and peritonitis. The prognosis for all types of rectal prolapse depends on early identification and reduction of the prolapse. Prolapses of types I and II that can be managed conservatively have a favorable outcome. Surgical correction of types I and II also carries a good prognosis but with a higher incidence of postsurgical complications. Because of the cost of surgical repair, market animals often are slaughtered if conservative management fails. Rectal prolapses of types III and IV carry a fair to guarded prognosis, which depends on the extent of tissue involvement and viability, the surgeon's skill, and postsurgical complications.

33 Chapter 33 Diseases of the Hepatobiliary System

Consulting Editors

Erwin G. Pearson

33.1 DIAGNOSIS OF LIVER DISEASE

ERWIN G. PEARSON

In making a diagnosis, the clinician should first determine that the animal has liver disease and then try to identify the specific cause. Therefore, this chapter first discusses the diagnosis of liver disease, then the individual conditions causing disease. The liver cannot be examined directly in large animals. The signs of liver disease are caused by failure of some of the liver's many functions, but these signs may not appear in the early stages of disease. Special tests may be needed to detect early damage or minor impairment of function that has not yet produced clinical signs.

33.2 LIVER DISEASE VS. LIVER FAILURE

As with many other organs, such as the heart and kidney, the liver can be diseased long before it fails to function. Thus, early cases of liver disease are not apparent to the owner or veterinarian through physical findings alone; such cases usually are detected by finding elevated levels of liver enzymes or bile acids in the serum. Pathologic changes in the liver may include biliary hyperplasia, death of hepatocytes, and fibrosis, and these may occur long before any signs of failure develop. Some functions may fail before others, and the onset of liver failure varies with the species and the disease process involved.

33.3 LIVER RESERVE AND REGENERATION

The liver has a large reserve capacity, and close to 80% of it can be removed before regeneration and recovery are no longer possible. It also has a remarkable capacity to regenerate. Regeneration can occur in areas receiving portal blood, but most cell division takes place in Rappaport zone 1 (the portal area), and the cells are pushed to the central lobular area. The liver undergoes constant repair, and in people it is estimated that the hepatocytes are renewed every 50 to 75 days.[1]

Normal regeneration does not occur in some cases. Antimitotic agents such as metabolites of pyrrolizidine alkaloids or antineoplastic drugs can prevent cell division. Regeneration may be restricted by connective tissue. Once fibrosis has bridged the various lobules, additional regeneration is impaired because the fibrosis itself perpetuates the condition. Loss of a stroma to build on or lack of portal blood supply also reduces regeneration.

33.4 SIGNS OF LIVER DISEASE AND PATHOPHYSIOLOGY

Many signs can be present with liver disease, but no sign is pathognomonic or present consistently. Table 33-1 provides some of the signs that may be present and other possible causes of the same signs.[2]

The clinical history is useful in some cases, but consumption of pyrrolizidine alkaloid—containing plants may not be apparent because of the delay between consumption and the onset of clinical signs. Exposure to other

hepatotoxins could be detected. Ruminants grazing on land infested with snails are more likely to have liver fluke disease. Administration of horse serum to Equidae 4 to 8 weeks previously will make acute serum hepatitis more likely.

With the exception of pain over the liver elicited with pressure and change in liver size, most signs are related to failure of some function. Liver flukes may cause anemia and hypoproteinemia because of the effect of the parasite and its metabolites. Liver abscesses and other infections may produce signs such as fever and anorexia because of the release of pyrogens and other mediators (caused by the organism and not necessarily related to the liver itself).

Icterus is typically seen in acute liver disease in horses but is not seen in many cases of chronic liver disease, and it is seen less often in ruminants unless biliary blockage occurs. Icterus is caused by failure of uptake, conjugation, or excretion of bilirubin. Excess production caused by hemolysis must also be considered when icterus is present, and is the most common cause of icterus in cattle. Horses are frequently icteric (up to 6 mg/dL unconjugated bilirubin) from anorexia or fasting even when the liver is normal.

Weight loss is a common but nonspecific finding in some cases of chronic liver disease. It may be caused by anorexia or failure of metabolic functions of the liver and is probably not related to impaired fat absorption in the large herbivores. *Diarrhea* is also seen, especially in cattle with chronic liver disease. It is thought to be related to portal hypertension and increased hydrostatic pressure, although the exact mechanisms are not yet understood. Diarrhea probably is not caused by fat malabsorption or steatorrhea, because the normal herbivore diet contains less than 3% fat.

Ascites is a common finding in calves with liver cirrhosis. The ascites results from portal hypertension caused by venous blockage producing increased hydrostatic pressure and by protein leakage into the peritoneal cavity. Production of hepatic lymph high in protein (>3 g/dL) is increased. Because the liver sinusoids are permeable to plasma proteins, the protein-containing lymph leaks into the interstitial space and then into the peritoneal cavity.[3,4] Fluid moves into the abdominal cavity because of both osmotic and hydrostatic forces, according to Starling's law. The abdominal fluid present with liver disease is a modified transudate, but the protein content may be relatively high (3 to 3.5 g/dL) because of leakage of protein from the liver. Hypoalbuminemia can aggravate the ascites, but if it occurs alone, it more likely will cause intramandibular and brisket edema.

Table 33-1 Signs of Liver Disease or Failure

Sign	Pathogenesis	Other Causes
Icterus (E)	Failure of uptake, conjugation, or excretion of bilirubin	Massive hemolysis Bile blockage Fasting in the horse
Weight loss (E, B)	Energy demand greater than absorbed or metabolized	Poor nutrition, chronic inflammation, parasites, neoplasia, maldigestion, malabsorption
Ascites (B)	Portal hypertension and lymph leakage caused by cirrhosis or venoocclusion	Cardiac failure Hypoproteinemia Cushing's syndrome
Change in liver size	Nodular hyperplasia, tumor, cirrhosis Fatty degeneration	Right-sided heart failure Work hypertrophy Anemia
Diarrhea (B)	Bile deficit malabsorption Intestinal edema, portal hypertension	Gastrointestinal (GI) or systemic disease
Pruritus	Retention of bile salts	Dermatologic or central nervous system (CNS) disorders
Dermatitis Unpigmented areas	Hepatogenic photosensitization	Primary phototoxic photosensitization
Central nervous system signs Behavioral change, ataxia, dysmetria, circling, stupor, coma, tremors, bellowing	Hepatic encephalopathy (see text)	Brain diseases Metabolic diseases Toxic diseases
Tenesmus (B)	Hepatic encephalopathy	Rectal or colonic disease CNS disease Urogenital disease
Rectal prolapse (B)	Tenesmus	Rectal or colonic disease
Change in feces color	Bile pigment deficit	Diet
	Undigested fat	GI disease
Hemorrhage	Failure to synthesize clotting factors II, V, VII, IX, X	Other clotting factor or platelet deficit, trauma, disseminated intravascular coagulation
Pain over liver	Inflammation, swelling	Abscesses Traumatic reticulitis
Inspiratory stertor (E)	Hepatic encephalopathy	Upper airway obstruction
Dyspnea		

E, Frequent sign in horses; *B,* frequent sign in cattle.

Dermatitis of the white areas may occur because of hepatic photosensitization. The skin of the white areas first becomes erythematous, then thickened with keratin crusts, and finally necrotic. This is caused by the photodynamic agent *phylloerythrin,* which is formed in the gastrointestinal (GI) tract of herbivores by the bacterial degradation of chlorophyll. After absorption into the portal circulation, phylloerythrin should be conjugated by the liver and excreted into the bile. With cholestasis, the phylloerythrin may be carried to the skin, where it acts as a

photodynamic agent.[5] After bile duct ligation, the level of phylloerythrin steadily increases.[6] Although a small amount is removed by the kidneys, the rate is not fast enough to prevent accumulation in the plasma and the skin. Phylloerythrin in the skin reacts to sunlight and emits energy that causes lesions of the white areas.[5]

Pruritus is seen in a few cases of liver disease in horses. In people, pruritus is assumed to be caused by bile acid accumulating in the skin when it is not excreted by the liver. This same process may occur in horses, but pruritus is not usually seen in large animals with liver disease.

A change in fecal color is not usually noted in adult herbivores with liver disease because other pigments such as chlorophyll contribute to the color. In young animals with simple digestive tracts, much of the fecal color is from *stercobilin,* a metabolite of bilirubin. Therefore, with cholestasis, the feces may be a lighter color.

A few signs may be seen terminally in liver disease. Hemorrhage may occur when the clotting factors are not synthesized in adequate amounts. Factors I, II, V, VII, IX, and X are all produced by the liver,[1,4] but the disease is usually advanced before a deficit develops.

Tenesmus, often followed by rectal prolapse, is seen in some cattle with liver disease. This may be associated with diarrhea, may be part of hepatic encephalopathy, or may be aggravated by edema of the bowel caused by portal hypertension.

Pharyngeal or laryngeal collapse with loud stertorous inspiratory noises and dyspnea has developed in some cases of hepatic failure, especially in ponies. The exact mechanism for this is not known, but it may also be part of hepatic encephalopathy.[7]

Horses sometimes develop a terminal hemolytic crisis caused by increased red blood cell (RBC) fragility. This has not been observed in ruminants.

33.5 HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy is a neuropsychiatric syndrome caused by hepatic dysfunction or portosystemic shunting of the intestinal blood.[8] It is considered a potentially reversible metabolic or neurotransmitter disorder, but it is associated with characteristic (although not specific) lesions in the central nervous system (CNS) such as altered astrocytes.

894

895

Signs of hepatic encephalopathy are often subtle and nonspecific. Behavioral changes may be detected by the owner, who is more familiar with the patient's normal activity. Some docile animals become excitable and difficult to control, whereas other, normally unruly animals may become passive. Depression and incoordination are frequent manifestations, and some animals may walk aimlessly or even head press.[9,10] Apparent blindness is seen in some horses, and foot stomping was reported in 7 of 25 cases.[11] The animals eventually develop a stupor and may end up in hepatic coma. Yawning may be seen in horses, and ponies may have a stertorous respiratory noise. Ruminants show signs of tenesmus and sometimes vocalize excessively. In humans, hepatic encephalopathy is diagnosed by neuropsychological tests, which are not possible in animals.[12]

The pathophysiology of hepatic encephalopathy remains undefined and is controversial.[10] It occurs when portal blood bypasses the liver, as with congenital shunts in dogs, or with shunts secondary to portal hypertension induced by alcoholic cirrhosis in humans, or when the blood goes through an inadequately functioning liver. How neurologic function is altered has not been determined, but speculation abounds.

It seems plausible to incriminate synergistic neurotoxins that bypass the liver. Most will agree that ammonia level plays a central role in the pathogenesis. Blood ammonia is elevated in most cases of hepatic encephalopathy because the liver is not metabolizing ammonia to urea. Encephalopathy can be precipitated in cirrhotic patients by adding ammonia-generating substances, and there is an increase in cerebrospinal glutamine, the product to which ammonia is detoxified. The astrocytes contain the enzyme *glutamine synthetase,* which adds a molecule of glutamate to ammonia to form glutamine. The amount of glutamine formed in the brain correlates with the severity of hepatifc encephalopathy.[13] However, much higher concentrations of ammonia are needed to induce coma in normal animals, and there is poor correlation between ammonia levels and degree of encephalopathy.[11] Four horses with hyperammonemia and encephalopathy without liver disease have been reported.[14]

Magnetic resonance imaging (MRI) of human cirrhotic patients revealed increased image intensities from the globus pallidus region, probably caused by manganese deposits.[12] Serum manganese is increased in these patients, which correlates with the increased MRI intensities and negatively with the neuropsycological tests. This would indicate that manganese is another potential toxin that can enter the brain if not effectively removed from the blood by the liver.

There may be an imbalance of true inhibitory and excitatory neurotransmission. γ-Aminobutyric acid (GABA) is an inhibitory neurotransmitter. The increase in GABAergic tone was originally thought to result from an increase in GABA or its receptor sites. More recently, it has been proposed that neurosteroids with GABA-agonist properties could be involved.[15] Ammonia is believed to play a role in the metabolism of GABA in the brain and thus could act synergistically.[16] Also, receptor sites for benzodiazepine are increased in the brain of animals with hepatic encephalopathy.[17] Benzodiazepine augments the activity of GABA in stimulating the inhibitory neuron and causing sedation.

False neurotransmitters have been proposed to cause the abnormal nerve function. Increased amounts of tryptophan, phenylalanine, and tyrosine in the brain could cause more *serotonin,* a false neurotransmitter, to accumulate in the brain. Plasma amino acid ratios are altered in horses with pyrrolizidine alkaloid—induced liver disease.[18] Concentrations of branched-chain amino acids (valine, isoleucine, leucine) are decreased, and the concentration of aromatic amino acids (tyrosine, phenylalanine, free tryptophan) are increased, partially because the liver is not adequately metabolizing the aromatic amino acids. The amino acids are transported across the blood-brain barrier by a common transport system, so they compete for entry into the CNS. It has been suggested that higher levels of aromatic amino acids in the CNS would lead to the formation of increased amounts of inhibitory neurotransmitters or to the alteration of catecholamine or monoamine neurotransmitters, such as GABA or L-glutamate.

33.6 LABORATORY TESTS AND LIVER-DERIVED SERUM ENZYMES

No single test can consistently confirm or rule out the presence of liver disease. Only serum concentrations of γ-glutamyltransferase, globulins, and alkaline phosphatase were found significantly different in horses with or without histologic evidence of liver disease in one study.[19] A combination of tests, including serum enzymes, total bile acids, and liver biopsy, may be needed.

Some blood constituents may be altered because of failure of certain metabolic functions of the liver, but none of these changes is specific for liver disease. Blood glucose is sometimes slightly lower in severe liver disease, especially in young animals, possibly because of decreased gluconeogenesis, but none of 28 adult cases in one

study had low blood glucose concentrations, and in fact, 14 cases had hyperglycemia.[11] Blood ammonia levels can increase fourfold or more in some toxic liver diseases because the urease needed to convert ammonia to urea is found only in the liver. For the same reason, blood urea nitrogen (BUN) may decrease, especially in the terminal phases. In the later stages, the blood-clotting factors may be diminished, with delayed partial thromboplastin time (PTT) and other clotting times.

Terminally, serum albumin concentration may decrease. A large amount of protein synthesis takes place in the liver; all the plasma proteins except γ-globulins are produced by the liver. The amount of these proteins in the blood, however, depends not only on the rate of synthesis but also on the rate of removal. The albumin half-life in cattle is about 16.5 days; in the horse, 19.4 days; and in sheep, 14 days.[20] Therefore, serum albumin is reduced mainly in chronic liver disease. With liver damage, the synthesis of α-globulins and β-globulins is increased so that the total plasma protein concentration is invariably normal or elevated, but the albumin/globulin (A/G) ratio may be decreased. The healthy liver has a large reserve for protein synthesis, and lost protein can be replenished. Less than 5% of horses with hypoalbuminemia had liver disease in a group from our teaching hospital. In one study, 18% of the horses with chronic liver disease and 6% of those with acute liver disease had albumin concentrations below the reference value.[21] In a British study, only 6 of 37 liver disease cases were hypoalbuninemic, and none of these was hypoproteinemic.[11] Therefore, it is assumed that hypoalbuminemia is not a common feature in horses with liver disease, and that hypoproteinemia is rare.

Amino acid ratios are altered in liver disease; the short, branched-chain amino acids are decreased, whereas the aromatic amino acids are increased.[18]

33.7 LIVER ENZYMES

A number of enzymes are compartmentalized in the hepatocyte or in bile duct epithelium. This compartmentalization is useful in holding insoluble molecules close to the enzymes for chemical reactions. Hepatocyte damage may result in release of the enzymes into the circulation, and cholestasis may cause increased release from bile epithelium. Serum levels of these enzymes therefore may be an indication of hepatocyte integrity or bile excretion. Table 33-2 lists frequently tested enzymes and their characteristics. Serum concentrations for some of these enzymes vary with the age of the animal and sometimes even with type or use. Table 33-3 lists some approximate upper limits of normal for animals of various ages. Normal values, especially for the enzymes, should be established by each laboratory. Chapter 22 provides normal adult values from one laboratory.

895
896

Table 33-2 Liver-Derived Enzymes

Enzyme	Specificity	Problems
GGT	Liver	High in young animals from colostrum
	Kidney*	
	Pancreas	
ALP	Liver	Not specific
	Bone	
	Intestine	
	Macrophages	
	Placenta	
SDH	Liver	Not elevated in chronic disease; short life; not stable
GLDH	Liver	Not elevated in chronic disease
AST (SGOT)	Liver	Not specific
	Muscle	
	Heart	
ALT (SGPT)	Liver	Low concentration in cattle and horses; not a good indicator in large herbivore
LDH	None unless isoenzymes	Not elevated in chronic disease; short life; not specific
OCT	Liver	Analysis not routinely available
Ar	Liver	Analysis not routinely available

GGT, γ-Glutamyltransferase; *ALP,* alkaline phosphatase; *SDH,* sorbitol dehydrogenase; *GLDH,* glutamate dehydrogenase; *AST,* aspartate aminotransferase; *ALT,* alanine aminotransferase; *LDH,* lactate dehydrogenase; *OCT,* ornithine carbamoyltransferase; *Ar,* arginase.

* Elevated in urine, not blood.

Table 33-3 Upper Limits for Normal of Some Liver Function Tests (from Various Sources)

Test	Sheep				Cattle				Sheep	Goat
Age	<1 wk	1-4	1-12 mo	Adult	<1 wk	1-4 wk	1-6 mo	Adult	Adult	Adult
Total bilirubin (mg/dL)	4.5	3.0	2.0	2.0	2.4	0.9	0.4	0.3	0.4	0.5
Direct bilirubin (mg/dL)	0.8	0.7	0.7	0.4	0.6	0.3	0.2	0.1	0.1	0.1
Total bile acids (μmol/L)	N/A	N/A	N/A	14	45	35	60	120	25?	N/A
BSP (half-life, T½min)	N/A	N/A	3.7	3.7	15	8	5	5	4.0	2.1
AST (IU/L)	600	540	700	270	60	60	60	60	110	80
GGT (IU/L)	170	170	40	30	4200	1300	N/A	24	55	50
ALT (IU/L)	2800	1200	840	194	1150	1000	N/A	81	188	386
SDH (IU/L)	8	8	N/A	5.8	N/A	N/A	N/A	15.3	28	23
GLDH (IU/L)	N/A	N/A	N/A	11	24	22	19	19	N/A	N/A
LDH (IU/L)	N/A	N/A	N/A	412	1380	1280	N/A	1445	440	392

N/A, Not available; *BSP,* Bromsulphalein (sodium sulfobromophthalein); *AST,* aspartate aminotransferase; *GGT,* γ-glutamyltransferase; *ALT,* alanine aminotransferase; *SDH,* sorbitol dehydrogenase; *GLDH,* glutamate dehydrogenase; *LDH,* lactate dehydrogenase.

γ-Glutamyltransferase (GGT) is a frequently tested and fairly specific enzyme that is almost invariably elevated in chronic liver disease. It is found mainly in the biliary tract and indicates biliary damage (flukes) or hyperplasia (pyrrolizidine alkaloid toxicity or aflatoxicosis). GGT also is present in pancreas, mammary gland, lung, kidney tubules, and other duct epithelium; but serum levels usually are not elevated with renal disease because the enzyme is lost in the urine. Serum concentrations are normally higher in neonatal calves (sometimes >4000 IU/L after suckling)[22] because the enzyme is concentrated in colostrum.[23] GGT levels are also higher in foals than in adult horses, but the higher concentrations may partly be the result of increased production.[24] GGT is elevated in many horses with right dorsal displacement of the large colon, possibly caused by transient extrahepatic bile duct obstruction.[25] Elevated GGT is the most sensitive indicator of liver disease in the horse.[11,26] GGT levels will remain elevated for several weeks.

Alkaline phosphatase (ALP) is usually elevated in chronic liver disease of the horse and is variable in ruminants. ALP can come from other sources, such as bone, intestines, placenta, and macrophages, so it is not specific. Both ALP and GGT are elevated with cholestasis.[27] The dehydrogenases, such as sorbitol dehydrogenase (SDH), lactate dehydrogenase (LDH), and glutamate dehydrogenase (GLDH), are found in hepatocytes and are elevated with acute hepatocyte damage, but serum concentrations may return to normal or below normal in chronic liver disease. SDH is liver specific and extremely useful in detecting active hepatocellular necrosis, but it is not as stable as some of the enzymes. LDH is found in many tissues other than liver; thus it is not specific unless isoenzymes are determined.

33.8 EXCRETION TESTS FOR FUNCTION

Because the liver excretes a number of endogenous compounds and foreign substances injected into the animal, the rate of excretion or clearance of these substances can be used to test the excretory function of the liver. Bilirubin itself can be used and, if elevated above normal, would indicate liver failure, bile blockage, or excess production from hemolysis. In the horse, bilirubin is also increased during fasting in animals without liver disease.[28] With liver damage in the horse or ruminant, most of the retained bilirubin is *unconjugated* (indirect reacting), and the direct-to-total ratio is usually less than 0.3. With bile blockage or intrahepatic cholestasis, the direct-to-total ratio may be greater than 0.3 in the horse or 0.5 in cattle.

896

897

Bilirubin is the main bile pigment and is produced from heme, 75% of which comes from RBCs.[29] When the erythrocytes are broken down, heme is converted first to biliverdin and then to bilirubin in the macrophage system. This unconjugated bilirubin is insoluble and must be bound to albumin for transfer, and this bound bilirubin is not removed by the kidneys. Unconjugated bilirubin is taken up by the hepatocytes with cytosolic binding proteins within the hepatocyte. In the hepatocyte, some bilirubin is conjugated to the diglucuronide, but in the horse, more than half the bilirubin in bile is conjugated with glucose. *Conjugated* (direct reacting) bilirubin is water soluble, and some will enter the general circulation; if concentration is sufficiently high, it will be filtered by the kidneys into the urine. Conjugated bilirubin is secreted into the bile canaliculi by an energy-dependent transport process. In most species, this is the rate-limiting step, but this may not be true in the large herbivores. Conjugated bilirubin passes into the intestine through the bile ducts, and if they are blocked, both conjugated and unconjugated bilirubin will increase in the plasma. In the intestinal tract, bilirubin is converted to urobilinogen by anaerobic bacteria. Some urobilinogen is absorbed and reexcreted by the liver, but a small fraction will pass the normal liver and be excreted in the urine. Therefore, with complete biliary blockage, there will be no urobilinogen in the urine, and with hemolysis, there may be increased urobilinogen in the urine. Urobilinogen is not very stable in the urine; thus analysis must be done within 1 or 2 hours, or the amount detected will be erroneously low.

Fasting decreases the efficiency of plasma bilirubin removal in all species, but the horse shows a greater rise in plasma bilirubin, often reaching a plateau two to three times the normal state. This increase is caused by a decrease in removal of bilirubin by the hepatic transport and not by an increase in its production.[30,31]

Serum total bile acid concentration is a good test of liver function. The concentration of bile acids in the serum will be increased if there is hepatocyte damage, blockage of bile flow, or shunting of portal blood to the systemic circulation, bypassing the liver. Bile acids are synthesized by the liver from cholesterol. Cholic and chenodeoxycholic acids are the primary bile acids that are conjugated with amino acids before excretion into the bile. Only conjugated bile acids are present in the intestine, are soluble, and form micelles with fat because of their detergent properties. Most of the bile acids excreted in the bile are resorbed by an active transport system in the ileum and carried by the portal circulation back to the liver for reexcretion. In most species, more than 95% of the

bile acids are resorbed and recirculated through the enterohepatic circulation.[32] The daily synthesis of bile acids is much less than the daily requirement, and one study in ponies showed that the bile acids secreted each day are about 38 times the total pool.[33]

Many simple-stomached animals have a postprandial increase in serum bile acid because of the release of bile from the gallbladder during eating and subsequent resorption by the ileum. This does not seem to be important in the horse, which has no gallbladder, or in cattle, in which no relationship to feeding could be found.[34]Table 33-3 lists upper limits of normal for liver function tests in large animals of various ages. In cattle there is an hour-to-hour fluctuation that could be as much as 60 μM/L.[34] In the horse, serum concentration above 14 μM/L would indicate liver damage, bile blockage, or shunting.[35,36] Serum total bile acid concentration is likely a more sensitive indicator of liver disease in the horse than serum bilirubin; only 8 of 34 horses with liver disease had elevated bilirubin, but 31 of 37 had elevated bile acids.[11] In adult cattle, because of the hour-to-hour variations, bile acid concentration on a single sample would have to be above 126 μM/L in beef cattle and 88 μM/L in dairy cattle to be an indication of liver disease.[37] Levels are lower (<64 μM/L) in calves less than 6 months old. Serum bile acid concentration is a very specific test that has a high positive predictive value.[38]

A number of dyes are excreted primarily by the liver; sulfobromophthalein (Bromsulphalein, BSP) is used most often. In large animals, BSP clearance (half-time) is used much more than the retention test. In the test, 500 to 1000 mg (~2 mg/kg) of BSP is injected intravenously. Blood samples are taken before the injection and two to four times 5 to 12 minutes after the injection (i.e., at 5, 7, 9, and 11 minutes). These samples are analyzed for color produced by BSP, and a half-life is determined by plotting the points on semilog paper. Normal horses have a BSP half-life of less than 3.5 minutes, and for ruminants it is less than 5 minutes. This may be increased in very young animals (see Table 33-3) and in pregnant females. Other dyes, such as indocyanine green, have some advantage (less renal excretion than BSP) but at present are too costly for use in large animals.

33.9 LIVER BIOPSY

Liver biopsy can be very useful not only in confirming the presence of liver disease, but also in determining or ruling out some etiologies. It is a relatively safe and simple procedure but should be avoided when liver abscesses are suspected. A number of biopsy instruments are available, including aspiration punches, but the Histo-Cut* or TrueCut† and similar notch-cutting needles seem to work quite well. In all species the skin over the biopsy site should be clipped and prepared for aseptic insertion of the needle. A local infiltration of 2% lidocaine helps to reduce the animal's reaction, but it may still flinch when the pleura and peritoneum are penetrated. A small stab wound is made through the skin at the site of insertion with a No. 11 or a No. 15 Bard-Parker blade. The horse should have a twitch applied or be given chemical sedation if necessary.

The site of skin puncture for liver biopsy in the horse is the right fourteenth intercostal space at the intersection of a line drawn from the tuber coxae to the point of the shoulder. Some operators recommend more cranial insertion (twelfth or thirteenth space), but more lung is penetrated at points farther craniad. If a more cranial position is selected, it should also be more ventral. If the needle is directed slightly craniad and ventrad, it is more likely to remain in the liver parenchyma and not penetrate larger vessels on the visceral surface or pass on through into the right kidney, pancreas, or colon. Ultrasound guidance will increase the chances of obtaining liver specimens without penetrating other organs.

Cattle need to be suitably confined for liver biopsy. A biopsy can often be performed on quiet dairy cows in a stanchion while the tail is elevated (“tailed”). The puncture site in cattle can be located by extending a horizontal

line craniad from the middle of the paralumbar fossa. The needle is inserted where this line crosses the eleventh intercostal space on the right side. The lungs do not extend as far caudad as in the horse, so the liver is more exposed. The needle is directed slightly craniad and ventrad, as in the horse.[2]

Liver biopsy in sheep and goats is slightly more difficult; additional sedation is usually required. A site at the ninth or tenth intercostal space at the level of the ventral end of the last rib has been recommended. The biopsy needle is advanced in a craniomedial direction until the liver is penetrated.

Diffuse or zonal lesions, as seen in most toxic, infectious, and metabolic liver diseases, can usually be diagnosed by liver biopsy. Focal lesions, such as abscesses, granulomas, and neoplasias, as well as liver flukes, are easily missed by liver biopsy. If a liver abscess is suspected, biopsy is contraindicated because of the potential danger of rupturing an abscess. A scoring system has been developed for the prognostic evaluation of equine liver biopsies.[39] Examining liver biopsy tissue can confirm the presence of liver disease and help establish the type of disease in addition to aiding in the prognosis.

* Jorgenson Laboratories, Loveland, CO.

† MWI, Meridian, ID.

33.10 ULTRASOUND EXAMINATION

Ultrasonographic examination of the liver is useful in determining its size, its situation, and the diameter of its vessels. Cholelithiasis, neoplasia, and fibrosis can be diagnosed by ultrasound in the horse.[40] Liver abscesses can often be detected, and the circumference of the gallbladder can be determined in cattle.[41,42] Parenchymal pattern of the liver is changed with diffuse fibrosis. An ultrasound examination is performed on cattle on the right side in the tenth to twelfth intercostal space. On sheep the examination is done on the right side in the seventh through twelfth intercostal spaces.[43] In horses the ultrasonic examination is performed below and caudal to the lung in the eighth to fourteenth intercostal spaces. The liver can also be visualized on the left side of the horse in the lower intercostal spaces. Horses with evidence of liver disease should have a percutaneous liver biopsy regardless of the ultrasonic appearance.[40]

33.11 PROGNOSIS

The severity of clinical signs may be the most useful noninvasive prognostic test in horses with liver disease.[44] Indicators of a poor prognosis in liver disease include an albumin concentration less than 2.5 g/dL in horses or an increased globulin level, a prothrombin time (PT) greater than 30% of normal, and greatly elevated GGT and ALP, especially if there is a normal or decreased SDH or GLDH. Marked fibrosis that bridges the liver lobules on histopathology suggests a poor prognosis. Severe pyrrolizidine alkaloid toxicosis carries a particularly grave prognosis because remaining hepatocytes are inhibited from regeneration by mitotic arrest. Terminal clinical signs include development of hemolytic crisis in the horse and marked hepatoencepalopathy in the patient with a fibrotic liver.

33.12 INFECTIOUS, TOXIC, AND PARASITIC LIVER DISEASE

33.12.1 ACUTE HEPATITIS IN HORSES

Nat T. Messer IV

Idiopathic acute hepatic disease (IAHD) is the most common cause of acute hepatitis and hepatic failure in horses.[45] IAHD is also known as Theiler's disease,[46] serum hepatitis,[47] postvaccinal hepatitis,[48] and acute liver atrophy.[49] The disease was first recognized by Theiler in large numbers of horses in South Africa following immunization against African horse sickness with simultaneous administration of live virus and hyperimmune equine serum.[50] Since then, IAHD has been documented as a potential complication of any equine serum or plasma product used in horses. It is primarily a disease of adult horses[51] and recently has been most often associated with the use of either tetanus antitoxin (TAT) or commercial equine plasma.[47,49,52–55]

Mares appear to be affected with IAHD more frequently than males, with recently parturient, lactating mares at greatest risk.[51,54] The seasonal nature of some epidemics of IAHD[51,56] (most reported cases occur in summer months) and the observation that some affected horses in outbreaks of IAHD have not been treated with TAT or plasma[45,51,56] have led to the concern that a virus is involved, similar to hepatitis B virus in humans, but this remains unproved.[46] Alternatively, IAHD has been proposed to be a type III (immune complex—mediated) hypersensitivity reaction.[57]

The clinical effects of IAHD are associated with signs of acute hepatic failure and include depression, jaundice, inappetence, pica, yawning, photoactive dermatitis, and hepatic encephalopathy.* Fever has been described as absent or rare in horses affected with IAHD.[48] Atypical signs that have been reported include progressive weight loss, ventral subcutaneous edema, jugular pulses, ileus, and acute respiratory distress.[54,55,59] Intravascular hemolysis has been reported to lead to hemoglobinuria in some terminal cases of IAHD.[46] Evidence exists for a subclinical or chronic component in some cases of IAHD.[54,60] However, some horses that received TAT have clinicopathologic evidence of liver dysfunction without developing clinical signs, indicating that disease severity may vary.[49,54,60]

Diagnosis of IAHD is based on the anamnesis, clinical signs, and findings from serum biochemical analysis, hepatic biopsy, and necropsy. High serum levels of unconjugated and total bilirubin and serum bile acids, coupled with high serum activity of GGT, SDH, aspartate aminotransaminase (AST), LDH, and ALP, are indicative of hepatic necrosis in horses. IAHD may be confirmed by hepatic biopsy or postmortem examination of hepatic tissue. Typical histopathologic changes seen in biopsy specimens or obtained at postmortem examination include widespread necrosis of hepatocytes that is most severe in the centrilobular and midzonal areas, with the few living cells confined to the periportal areas.[53] The normal architecture of the centrilobular and midzonal areas is replaced by a pale, eosinophilic granular mass in which ghost outlines of necrotic hepatocytes are present.[53] A mild inflammatory cell infiltrate is seen in the portal areas, as well as a number of spindle-shaped fibroblastic cells.[53] The histopathologic lesion is frequently more advanced than the clinical course of the disease would suggest.[53]

There is no specific treatment for IAHD.[61] Treatment should be aimed at supporting liver function and controlling abnormal behavior. Dietary adjustments are important and should consist of reducing the quantity of protein in the diet while increasing carbohydrate intake.[46] Sorghum, milo, or beet pulp, which contains high levels of branched-chain amino acids, can be mixed with molasses to improve palatability and caloric content.[46] Diets high in branched-chain amino acids tend to lessen the degree of abnormal behavior associated with hepatic encephalopathy.[61] Oral neomycin, lactulose, and mineral oil may be administered to decrease ammonia production and absorption from the GI tract. It may become necessary to sedate horses that display severe signs

of hepatic encephalopathy with xylazine or detomidine.[61] Continuous intravenous (IV) administration of dextrose and balanced electrolyte solutions to reduce hepatic workload and maintain plasma volume is recommended.[60] If spontaneous bleeding occurs at injection sites or at sites of self-inflicted injury, plasma transfusions may be necessary to replace the deficient clotting factors.[46] The use of glucocorticoids for treating IAHD is controversial but may be indicated based on some histopathologic evidence of an immune-mediated etiology.[57]

Although the cause of IAHD is unknown, the administration of TAT to recently parturient, lactating mares is associated with substantial risk for development of fatal IAHD.[51,54,60] The susceptibility of postparturient mares to IAHD after TAT administration at foaling is unexplained. Postparturient mares may be the most likely adult horses to receive TAT. Therefore the use of TAT is not without risk, and its use should be restricted to clinical situations necessitating tetanus prophylaxis and in which a history of active tetanus (toxoid) immunoprophylaxis is absent or unknown. The risk of postvaccinal IAHD should be addressed with the owner before administration of TAT.

Routine administration of TAT to parturient mares should be strongly discouraged, and the routine use of active tetanus immunoprophylaxis should be reemphasized. Although the prevalence of serum hepatitis associated with administration of commercial plasma appears to be low in the horse, it should be considered an uncommon risk that can have a fatal outcome.[55] IAHD may be observed sporadically or may affect a group of horses. Recognition of IAHD in one horse should necessitate careful observation of horses on the same premises for either clinical or serum biochemical signs of IAHD.[60] Based on recent case reports, it appears that not all cases of IAHD are clinically apparent and that screening for its presence utilizing routine serum biochemical analysis is useful in detecting subclinical cases of IAHD.[54,55,60]

33.12.2 BLACK DISEASE

Joseph H. Snyder

Stanley P. Snyder

33.12.2.1 Definition and Etiology

Black disease *(infectious necrotic hepatitis)* is a disease of grazing animals, primarily sheep, resulting most often in sudden death.[62–65] It is caused by toxins produced by the bacterium *Clostridium novyi* type B. *C. novyi* occurs in soils and is normally present in the digestive tracts and livers of animals grazing affected pastures. Disease occurs only when there is sufficient liver damage to provide the anaerobic environment required for growth of the organism and subsequent toxin production. In practice, the liver insult is almost always caused by larval migration of the common liver fluke, *Fasciola hepatica*. Therefore, this is a seasonal disease related to the liver fluke cycle and occurring in animals typically infested by *F. hepatica*. Other liver parasites, such as *Fascioloides magna, Dicrocoelium dendriticum,* and *Cysticercus tenuicollis,* are occasionally implicated, as is damage to the liver by biopsy or trauma that is severe enough to result in localized anaerobiosis in the liver, but these cases are rare. Such a scenario should be considered when sudden deaths occur at times flukes are not usually migrating or in families such as Equidae that are not normal hosts for *F. hepatica*. The disease occurs worldwide where liver flukes are present. The *C. novyi* strains that cause black disease produce at least three potent exotoxins: the *alpha-toxin,* which is the classical lethal toxin; the

beta-toxin, which has both lethal necrotizing and hemolytic lecithinase activities; and the *zeta-toxin,* which is hemolytic.[66]

33.12.2.2

Pathophysiology

C. novyi type B is widely distributed in soils, and its spores are continuously ingested and shed in feces of grazing animals. Some of these organisms cross the intestinal mucosa and become disseminated throughout the animal's mononuclear macrophage system, including the Kupffer's cells of the liver. When localized anaerobic conditions occur in the liver, as with migration of liver fluke larvae, these resident spores may germinate and enter a vegetative state. As they proliferate, they release their toxins and create enlarging zones of coagulation necrosis in the liver. The exotoxins produced will enter the general circulation, where they cause damage to neurons, vascular endothelium, and other vital cells and tissues, eventually causing sudden death of the animal.

33.12.2.3

Clinical Signs

Clinical black disease consists almost entirely of animals found dead. In the unlikely event that an affected animal is recognized before its demise, the signs are nonspecific. The animal will often be off to itself and will appear depressed, anorexic, and possibly in respiratory distress. Temperature is elevated initially, 40° to 41° C (104° to 106° F), but declines before death. Unlike closely related bacillary hemoglobinuria, or “redwater,” affected animals do not show red urine or bleeding from nose or rectum. Diagnosis of clinical black disease can often be accomplished at necropsy or with the help of simple laboratory tests. History will include sudden death, usually in an endemic area during warmer weather, when fluke transmission is active. Flock or herd vaccination will be either overdue or absent. It is also helpful to know the history of fluke infestation on the farm and the timing of fluke control measures, if any have been taken. Time of death should be ascertained as closely as possible. The animal is usually presented in lateral recumbency without signs of struggle. It will be severely bloated, even if death has occurred quite recently, and gives the impression of a carcass in a more advanced state of decomposition than timing would suggest.

33.12.2.4

Necropsy Findings

Postmortem lesions are often obscured by rapid putrefaction of the tissues. Skinning the animal reveals engorgement and hemorrhage of subcutaneous blood vessels, resulting in “black” discoloration, thus the name of the disease. Once the body cavity is entered, blood-tinged abdominal, thoracic, and pericardial fluids are present. Urine is grossly normal. Subendocardial and subepicardial hemorrhages are present. There may be hemorrhages on serosal and pleural surfaces, but these are not always present. Tissues, especially solid organs such as liver and kidney, appear to be in a state of autolysis much more advanced than time of death would suggest. In addition to the presence of migrating fluke channels, the liver is swollen and congested and has one to several small, pale areas of coagulative necrosis. These lesions are typically along the diaphragmatic surface of the liver, have hyperemic borders, and extend for a variable distance into the hepatic tissue. Careful slicing of the organ may be required to find these lesions.[64]

33.12.2.5

Diagnosis

If necropsy does not confirm a diagnosis of black disease, or if there is need for additional documentation, a simple Gram stain of an impression smear taken from the margin of the liver lesion or from any area of a liver

without lesions will reveal numerous large, gram-positive rods typical of the clostridia. Because clostridial organisms proliferate rapidly after death, such findings must always be interpreted carefully, with consideration of time elapsed between death and necropsy. Further diagnostic measures include anaerobic culture and isolation of *C. novyi* type B, identification of the specific toxins, and fluorescent antibody identification of the organism. Characteristic histopathologic changes may also be seen in fixed sections of liver associated with necrotic lesions. Impression smears obtained from the liver lesions are ideal for the fluorescent antibody identification of *C. novyi* type B. Specific toxin identification is impractical for most laboratory settings but is the confirming procedure of choice. 900

33.12.2.6 Treatment and Prevention

Treatment of black disease is rarely undertaken because of its acute to peracute presentation, with animals usually found dead. *C. novyi* is highly sensitive to penicillin and the tetracyclines, but toxin production is usually too far advanced for antibiotics to be of value. If used, they should be administered at high doses, intravenously if possible for most rapid onset (20,000 IU/kg crystalline penicillin or 5 mg/kg oxytetracycline), followed by intramuscular (IM) or IV doses at appropriate intervals. Supportive IV and/or intraluminal fluid therapy should be initiated to correct dehydration. Antiserum is not available. Care should be exercised in handling affected animals because stress may result in sudden death. Chances of success are small. In the event of an "outbreak," vaccination should be initiated immediately, along with mass administration of penicillin or tetracycline, preferably in a long-acting form.

A good prevention program requires consideration of both the pathophysiology and immunology of the disease and the natural history of the liver fluke *(F. hepatica)* that is so intimately involved in expression of black disease. Efforts to clear soils of the offending organism are unrewarding. However, it is recommended that carcasses of animals dying from black disease be burned, buried deeply, or removed from the premises.

Commercial bacterin/toxoids against *C. novyi* are available in combination with other clostridial vaccines. These products are generally safe and highly efficacious. Duration of protection is short, however, and should not be relied on more than 5 to 6 months. Field experience suggests that monovalent *Clostridium haemolyticum* vaccine is more effective than combination products in high-risk herds, and efficacy may vary among commercially available combination vaccines. Animals vaccinated when less than 3 to 4 months old require revaccination at weaning. Local reactions at the site of subcutaneous vaccination are common but primarily of cosmetic concern. Intramuscular vaccination should be avoided because it frequently results in permanent damage to muscle tissue, with a negative impact on meat marketing. Timing of vaccination must be determined by the local climate and liver fluke season. In more severe climates where the fluke season is relatively short, a single annual injection before fluke transmission season may suffice. In more moderate climates with longer periods of fluke exposure, a second injection about 5 months later may be required.

Control of liver fluke infestation is closely linked to prevention of black disease. Control measures include pasture or range management; control of water sources; limiting access to streams, canals, ponds, and marshes; and strategic treatment of animals with products effective against flukes. Appropriate disposal of infected carcasses is important. This is a complex subject, and the reader should refer to the section on liver flukes for more detail.

33.13 Bacillary Hemoglobinuria ("redwater")

Joseph H. Snyder

Stanley P. Snyder

33.13.1 Definition and Etiology

Bacillary hemoglobinuria (redwater, icterohemoglobinuria) is a disease causing sudden death in cattle and other ruminants and, rarely, horses. It is caused by the toxins of *Clostridium haemolyticum* (*Clostridium novyi* type D). This organism is closely related to the etiology of black disease, in which toxin production is closely linked to bacteriophage infection of the clostridial organisms.[67] The major biologically active toxins in *C. novyi* type D (*C. haemolyticum*) are the *beta-toxin,* which is a phospholipase C and has both lethal necrotizing and hemolytic lecithinase properties; the *zeta-toxin,* which is a tropomyosinase; and the *theta-toxin,* which is a lipase. Prominent actions of the toxins induce localized hepatic necrosis and intravascular hemolysis. *C. haemolyticum* occurs in soils, and its spores are routinely found in the livers and passed in the feces and urine of healthy animals grazing affected pastures. Disease occurs only when there is sufficient insult to the liver to provide the anaerobic conditions required for bacterial growth and toxin production. In almost all cases the liver insult is caused by migration of *Fasciola hepatica* (common liver fluke) larvae.[68–70] As in black disease, *Fascioloides magna, Dicrocoelium dendriticum* (the lancet liver fluke), and *Cysticercus cellulosae* have also been occasionally implicated in the disease, as has liver biopsy or trauma severe enough to result in bruising of the liver.[71] Redwater is then, for all practical purposes, a seasonal disease occurring at the time of larval fluke migration.

Bacillary hemoglobinuria is a regionalized disease. It has been reported that *C. haemolyticum* is limited to alkaline soils, but the disease is also endemic in regions with acid soils. The factors affecting distribution of the disease are not well understood. Even in areas where it is common, distribution is erratic, with some farms severely affected, whereas others nearby are disease free. The disease is expanding from areas where it has traditionally been seen, probably in large part because of the shipment of cattle carrying *C. haemolyticum* and *F. hepatica*.

33.13.2 Pathophysiology

Spores of *C. haemolyticum* are ingested by susceptible animals, cross the intestinal mucosa, and are transported to the liver and other organs, probably within the phagosomes of cells of the mononuclear macrophage series. The spores can persist for long periods in the liver within Kupffer's cells. Any localized area of anaerobiosis, as caused by migrating fluke larvae, allows these spores to germinate and proliferate. Release of toxins from the vegetative cells further increases the anaerobic environment, favoring accelerated bacterial proliferation, toxin production, and hepatic necrosis. Absorption of toxins into the circulatory system rapidly leads to intravascular hemolysis, icterus, hemoglobinuria, and death.

33.13.3 Clinical Signs

In most cases of bacillary hemoglobinuria, animals are found dead. In the rare cases in which disease is recognized antemortem, signs include malaise (animal by itself, “humped up,” reluctant to move), anorexia, and fever of 40° to 41° C (104° to 106° F), declining as death approaches. Breathing may be rapid and shallow, and blood or blood-tinged froth may be present in the nostrils. Rectal bleeding or bloody feces may also be observed. The eponymous sign is passage of dark-red, “port wine”–colored urine (hemoglobinuria), but this sign is seen relatively infrequently. Blood is thin and watery and coagulates slowly. Mucous membranes are pale and icteric. Severity of signs increases as the disease progresses.

Bacillary hemoglobinuria is usually diagnosed at necropsy as a cause of sudden death. Historical concerns include occurrence in or origination of the animal from an endemic area, season of the year, last known sighting of the live animal, approximate time of death (and time from estimated death to necropsy), and farm history of vaccination and liver fluke control. Frequently the animal has been seen apparently healthy 12 to 24 hours before death. Herd vaccination is either nonexistent or overdue. The animal is usually in lateral recumbency, severely bloated, and without signs of struggle. Blood is often present in the nostrils, mouth, rectum, or vagina. The carcass appears to be in an advanced state of decomposition, even when it is actually quite fresh. A tentative diagnosis can be made on the basis of history and observation of the carcass.

33.13.4 Necropsy Findings

On closer examination, membranes and tissues are icteric. Skinning the animal reveals numerous subcutaneous petechial and ecchymotic hemorrhages, edema, and sometimes emphysema. There will be copious amounts of red-tinged abdominal and thoracic fluid. Hemorrhages are present on all serosal surfaces. Dark-red urine (or traces) is present in the bladder. Lymph nodes are congested and usually hemorrhagic. There may be hemorrhage into the bowel lumen. The spleen is enlarged. The tracheobronchial tree is usually filled with blood-tinged froth or foam. Lungs show hemorrhages, edema, and frequently emphysema. Pericardial fluid is blood tinged, and hemorrhages are present on both the epicardium and the endocardium. Solid organs such as liver and kidney appear to be in advanced stages of autolysis, even in fresh carcasses. The confirming (pathognomonic) lesion is the so-called ischemic hepatic “infarct,” which has a zone of hyperemia at its interface with viable liver tissue. This area of coagulative necrosis, sometimes partially liquefied at its center, can reach up to a 30-cm diameter and have a very irregular outline.[69] Unlike a classic infarct, the lesion in bacillary hemoglobinuria results from the progressive enlargement of the focus of coagulative necrosis caused by the bacterial toxins. Any thrombosis seen in the lesion is secondary, with the vasculature being included in the necrotic process, along with other hepatic tissue.[71] A thin coat of fibrin may cover the capsule of the liver where it overlies the necrotic lesion.

33.13.5 Diagnosis

In most cases, diagnosis of redwater can be confirmed at necropsy. Some peracute cases may be less typical, or laboratory confirmation may be needed in certain, unusual cases. A simple Gram-stained impression smear from the liver will reveal numerous typical clostridial organisms. Smears may also be made from spleen, blood, or abdominal fluid, with the same outcome. Postmortem presence of clostridial organisms must be interpreted with caution because they are always present and proliferate rapidly after death. It is important to have an accurate estimate of time of death to determine the significance of these findings. Laboratory confirmation depends on identification of the causative bacterium. Both fresh (refrigerated) and formalin-fixed liver lesions should be submitted. Fluorescent antibody tests on impression smears taken from a liver “infarct” will be positive for *C. novyi* type D antigens. Extensive biochemical and toxin identification tests are confirmatory but are seldom used if lesions and fluorescent antibody tests are compatible. Histopathology reveals numerous clostridial rods within the hepatic lesion, particularly immediately subjacent to the zone of neutrophils at the advancing margin of the lesion.

33.13.6 Treatment and Prevention

Treatment of bacillary hemoglobinuria is seldom undertaken because of the acute nature of the disease. If there is opportunity for treatment, penicillin at high dosages (at least 20,000 IU/kg IM twice daily) is the antibiotic of choice, although tetracyclines (5 mg/kg IV twice daily or 10 mg/kg IM daily) are acceptable. Because time is

critical, initiating treatment with crystalline penicillin IV (20,000 U/kg) is indicated if available. Fluids are given intravenously (IV) or intraruminally to correct dehydration. Because of severe hemolytic anemia, blood transfusion is advisable and should be repeated as necessary. Affected animals must be handled with great care because stress or excitement may result in sudden death. In the rare instance of recovery, hematinics should be given to support RBC regeneration.

An effective prevention program requires consideration of both the pathophysiology and immunology of the disease and the natural history of the liver fluke *(F. hepatica)* that is so intimately involved in expression of bacillary hemoglobinuria. Efforts to clear soils of the offending organism are unrewarding. However, it is recommended that carcasses of animals dying from bacillary hemoglobinuria be burned, buried deeply, or removed from the premises.

Commercial bacterin/toxoids against *C. haemolyticum* are available in both monovalent form and in combination with other clostridial vaccines. These products are generally safe and highly efficacious. Duration of protection is short, however, and should not be relied on more than 5 to 6 months. Animals vaccinated when less than 3 to 4 months old require revaccination at weaning. Local reactions at the site of subcutaneous vaccination are common but primarily of cosmetic concern. Intramuscular vaccination should be avoided because it frequently results in permanent damage to muscle tissue, with a negative impact on beef marketing. Timing of vaccination must be determined by the local climate and liver fluke season. In more severe climates where the fluke season is relatively short, a single annual injection before fluke transmission season may suffice. In more moderate climates with longer periods of fluke exposure, a second injection about 5 months later may be required.

Control measures include pasture or range management; control of water sources; limiting access to streams, canals, ponds, and marshes; and strategic treatment of animals with products effective against flukes. This is a complex subject, and the reader should refer to the section on liver flukes for more detail.

33.14 HEPATIC FAILURE IN FOALS

Thomas J. Divers

Hepatic failure in foals might result from infectious, parasitic, congenital, metabolic, or toxic causes. Iron fumarate is the best documented of the toxic causes.[72] Iron toxicity most often occurs when newborn foals are given iron before nursing. Colostral-acquired glutathione or other protective substances may explain the great decrease in iron hepatotoxicity when the iron is administered after colostrum.[73] When the iron is given at birth and before colostrum, clinical signs develop 2 to 5 days later. In rare cases, clinical signs may not develop until the foal is older. The initial clinical signs are associated with hepatoencephalopathy and include seizures, marked depression, ataxia, aimless wandering, head pressing, or any sign of abnormal behavior. Icterus is noted in most foals at the time neurologic signs are exhibited, although some foals may die so peracutely that icterus is not noticed. Although not documented in foals, nonsteroidal antiinflammatory drugs (NSAIDs), such as carprofen and mycotoxins, are other potential toxic causes of hepatic failure. Rarely, foals treated with macrolides, trimethoprim-sulfas, or histamine-2 (H_2) blockers for pneumonia or diarrhea develop an increase in serum hepatic enzymes, despite the foal improving clinically. With changes in drug treatment, the serum enzymes return to normal, suggesting these cases may have drug-induced hepatopathy.[74] Steroid-induced hepatic lipidosis has been observed in foals receiving both prolonged and high doses of corticosteroids.

901

902

Other causes of hepatic failure in foals include perinatal herpesvirus infection, leptospirosis, *Actinobacillus equuli* infection, streptococcal bacteremia, Tyzzer's disease, other bacterial infections, systemic inflammatory response syndrome (SIRS) and multiple organ system dysfunction, septic portal vein thrombosis (e.g., *Rhodococcus equi*),

chronic neonatal isoerythrolysis, hepatic lipidosis/hyperlipemia in miniature equine foals, cholangitis associated with duodenal ulcer disease, *Parascaris equorum* migration, congenital anomalies (e.g., atresia of bile duct, portosystemic shunts), and hyperammonemia in Morgan weanlings.

Equine herpesvirus 1 (EHV-1) infection of a near-term fetus may result in the birth of a nonviable foal with hepatic, respiratory, and/or gastrointestinal disease.[75] Generally, the clinical condition rapidly declines within 5 days after birth. Affected foals may have severe neutropenia and lymphopenia. Treatment with oral acyclovir (8 to 16 mg/kg every 8 hours) may improve survival rates.[76]

Leptospirosis was reported to cause jaundice and death in a 10-day-old foal.[77] Although *Leptospira pomona* is known to cause abortion and liver disease (giant cell hepatopathy) in the equine fetus, it is also apparently a rare cause of neonatal liver disease. *A. equuli* typically causes bacteremic embolic nephritis and acute death in very young (~3-day-old) foals. It may also cause widespread multifocal hepatitis in foals. *Streptococcus zooepidemicus* bacteremia may also cause multifocal hepatic abscesses. *Tyzzer's disease* is the best-documented cause of bacterial hepatitis in foals, as briefly discussed in the following section. Other bacteria and bacterial toxins may initiate an exaggerated response to sepsis (SIRS), which may result in multiple organ dysfunction, including hepatic failure. Many vasoactive mediators are involved in this process; the hemodynamic system becomes ineffective, and certain organs (e.g., liver) may fail because of hypoxia. Diffuse hepatic necrosis and hepatocellular apoptosis are the characteristic lesions. The clinical signs may be identical to Tyzzer's disease, except the syndrome may affect a much wider age range. Prompt and aggressive treatment is often successful. Appropriate treatments include broad-spectrum antibiotics, fluids, oxygen, and antioxidants such as dimethyl sulfoxide (DMSO) and acetylcysteine. Bacterial sepsis rarely may cause acute portal vein thrombosis. Variable degrees of hepatic hypoxemia and inflammation accompany the thrombosis. Hepatoencephalopathy does not generally occur in foals, unlike in adult horses, with portal vein thrombosis. Diarrhea may occur in foals from portal hypertension. The thrombus can be seen on ultrasound examination. A complete recovery may occur with long-term antimicrobial therapy.

Foals with severe and prolonged *neonatal isoerythrolysis* may develop liver failure,[78] which may result from a combination of chronic hypoxia and iron overload from multiple transfusions. Levels of conjugated bilirubin are generally high enough to suggest that bile stasis is also present. With severe and persistent hemolysis, bile excretion may become the rate-limiting step in bilirubin clearance. Physical obstruction of bile flow may result from duodenal scarring after a duodenal ulcer,[79] congenital biliary atresia, or parasitic obstruction.

Congenital *portosystemic shunts* occur infrequently in the equine and bovine.[80] Clinical signs may not be noted until foals are 2 to 3 months old and begin ingesting large amounts of grain or grass. Waxing and waning signs of encephalopathy are the most common signs in foals. Encephalopathic signs and tenesmus are characteristic of the disease in calves. Elevated plasma bile acids and ammonia levels in foals with encephalopathic signs and normal concentration of hepatic-derived serum enzymes should arouse suspicion of a portosystemic shunt. Shunts may be single or multiple and may be intrahepatic or extrahepatic. Positive-contrast portography is the diagnostic technique of choice. The shunt may also be detected by transrectal portoscintigraphy (in foals) or transabdominal ultrasound examination. Successful medical management followed by shunt ligation has been described in a foal and calf.[80,81]

Hepatic failure has been seen in Morgan foals.[82,83] The onset of clinical signs (depression and weight loss) occurred soon after weaning. Liver enzymes are elevated; and variable degrees of portal and bridging fibrosis with bile duct hyperplasia, karyomegaly, and cytomegaly are often seen on microscopic examination. The disease is fatal and may end with a terminal hemolytic crisis. The cause of the disease is unknown, but it may be inherited.

The best laboratory aids in confirming hepatic failure are abnormally high concentrations of serum bilirubin (both conjugated and unconjugated), ammonia, and prolonged PT. Elevation in serum enzymes that are hepatic specific may indicate hepatic disease. Some foals with toxic hepatic failure have had normal or only modestly elevated SDH levels. GGT levels may be high in normal neonatal foals.[84] Plasma glucose concentrations are frequently abnormally low in neonatal hepatic failure. The measurement of bile acids may be useful in determining hepatic dysfunction in foals older than 1 week.[85]

Treatment of these conditions is discussed later under Therapy of Liver Failure or under the specific condition.

33.15 TYZZER's DISEASE IN FOALS

Erwin G. Pearson

Tyzzer's disease is a sporadic, acute focal bacterial hepatitis that occurs in foals 7 to 40 days of age.[86] It has been reported in calves and other species.[87] The causative organism is *Clostridium piliforme,* formerly called *Bacillus piliformis*.[88] Multiple strains can infect Equidae.[89]

In many cases of Tyzzer's disease, the foal will be found dead with no previous signs of illness. The diagnosis in most cases is made postmortem. Recently, a polymerase chain reaction (PCR) test has been used to diagnose the condition in live foals.[90] If detected, clinical signs may include fever, icterus, depression, anorexia, diarrhea, and seizures, none of which is specific for the disease.[90,91] Serum chemistry values will show elevated liver enzymes, hyperbilirubinemia, hyperfibrinogenemia, and a severe hypoglycemia. Histopathologic examination of the liver reveals multifocal areas of necrosis in which the organism can be identified with the Warthin-Starry method.

There is one report of successful treatment of a proven case of Tyzzer's disease in a foal.[90] Early antimicrobial therapy and IV fluids to correct the severe hypoglycemia and acidosis, along with antiinflammatory drugs and parenteral nutrition, could be helpful.

33.16 CHRONIC ACTIVE HEPATITIS

Erwin G. Pearson

902

903

33.16.1 Definition, Etiology, and Epidemiology

Chronic active hepatitis represents a sustained inflammatory process within the liver. The diagnosis is made histologically when the principal features are infiltration of inflammatory cells into the portal areas, necrosis, and fibrosis.[92] Some pathologists do not recognize this as a large animal disease, and although there are few recent reports in the literature, a number of cases fulfill these criteria.

The etiology of chronic active hepatitis in large domestic animals is not known, but several factors likely are involved. In humans, persistence of the hepatitis B or hepatitis C virus accounts for most cases of chronic hepatitis. In dogs, most cases are reported to be “idiopathic,” even though more cases are reported.[93] In horses the histologic diagnosis is often cholangiohepatitis.[94] Cholelithiasis and cholangiohepatitis are encountered as forms of liver disease in adult horses and involve ascending infections from the small intestine.[95] These are discussed further under Choledocholithiasis, Cholelithiasis, Hepatolithiasis.

Cholangiohepatitis that is not associated with liver flukes also has been confirmed in cattle. Bacterial infection through the portal drainage of the bowel or by ascending infection from the bile duct is a potential cause of cholangiohepatitis. Toxins may play a role.[96] Immune-mediated processes are thought to be potential causal factors in humans and may be involved in horses because some respond to corticosteroids, but no definitive work has been done in large animals.

33.16.2 Clinical Signs and Differential Diagnosis

The signs of chronic active hepatitis are similar to those of other types of chronic progressive liver failure, as described previously under diagnosis. Progressive weight loss and depression associated with intermittent fever and icterus may be noted initially. Fever is most consistent with bacterial cholangiohepatitis. Other signs may develop progressively as liver functions begin to fail. Signs of concurrent intraabdominal diseases may be present, and some horses develop peculiar cutaneous lesions at the coronary band or areas of necrotic leathery skin.[97] These lesions usually appear as a moist, exfoliative dermatitis caused by an aseptic vasculitis. Differential diagnosis includes pyrrolizidine alkaloid toxicity, bile stones, abdominal abscesses, and other chronic wasting diseases.

33.16.3 Liver-Derived Serum Enzymes and Diagnostic Tests

Serum liver enzyme activities are usually elevated, reflecting active hepatocyte damage. ALP and GGT tend to be greatly elevated in the active stages of the disease process. Serum bile acid concentrations are increased, and the bromosulfophthalein clearance half-life is prolonged. In most cases, serum bilirubin, especially the direct reacting (conjugated) bilirubin, is elevated. A definitive diagnosis is made from histopathologic examination of tissue obtained by liver biopsy (see following discussion). A part of the liver biopsy, tissue should be submitted for bacterial culture and sensitivity. The lesion is described under Necropsy Findings.

33.16.4 Pathophysiology

The exact pathophysiology of chronic active hepatitis is not known. The early stages are associated with inflammation of the bile ducts and the portal areas of the liver. Extension of bacterial infection through the bile duct or through the portal venous drainage may be responsible for the lesion distribution in animals with suppurative cholangiohepatitis. When lymphocytes and plasma cells are predominant in the cellular infiltrate, immune-mediated processes are more likely.

The liver responds by proliferation of bile ducts and bile duct epithelium, which may impair bile excretion. Because hepatocytes are destroyed more rapidly than they are replaced, connective tissue takes their place. Eventually, areas are joined so that the fibrosis itself limits regeneration. At this stage, some cholestasis may occur, along with failure of other metabolic functions. Portal hydrostatic pressures could increase gradually, potentially leading to other clinical signs (e.g., ascites), but this has not been reported in large animals.

33.16.5 Necropsy Findings

Grossly, the liver appears firm and is often pale brown to green in color, and the cut surface may have prominent, irregular markings. Histologically, most of the lesions are present in the periportal areas. Inflammatory cell infiltration consists primarily of mononuclear cells in some cases, whereas a neutrophilic infiltrate that may contain bacteria (often coliforms) is found in others. These infiltrates are believed to indicate

the nature of the primary disease process. Biliary hyperplasia may be marked if there is cholangiohepatitis. Loss of hepatocytes and increased fibrous connective tissue may be pronounced in the periportal area.

33.16.6 Treatment and Control

Supportive care is most important in these cases, especially for the maintenance of proper appetite and nutrition (see Chapter 50).[98] General measures for treating liver disease apply in these cases (see p. 921). Corticosteroids have been especially useful in horses with a lymphocytic plasmacytic hepatic infiltrate. They act to increase appetite, stabilize cell membranes, and reduce inflammation and connective tissue formation. Initial treatment with dexamethasone at 20 to 40 mg/day for the first 4 to 7 days is followed by a gradual reduction in dosage rate over 2 to 3 weeks, depending on response to therapy.[99] Low-level treatment with prednisolone at 400 mg once daily may be required for an additional 2 to 4 weeks. Antibiotics are indicated when a bacterial cholangiohepatitis is suspected on the basis of the histologic features of the liver, the culture of the liver biopsy, and the presence of a persistent, intermittent fever. Although data are limited, enteric organisms are likely to be encountered, and antibiotic therapy should be directed at the likely organism. Bacterial culture and sensitivity from the biopsy specimen can guide appropriate antimicrobial therapy.

33.16.7 Prognosis

The prognosis for cases of chronic active hepatitis in the horse may be more favorable than with other liver diseases, such as toxicities and serum hepatitis. A recent retrospective study reported that five of nine horses with chronic active hepatitis survived.[100] Case records at Oregon State University Veterinary Teaching Hospital indicate that about half the cases of chronic active hepatitis with no evidence of *Senecio* poisoning improved. Liver biopsy and response to therapy are the best guides in formulating a prognosis. The prognosis for improvement and long-term survival is extremely poor in horses that have functional hepatic failure with widespread fibrosis and disruption of normal hepatic parenchyma. The prognosis is fair to good in patients with early (less severe) lesions, particularly those with a lymphocytic plasmacytic cellular infiltrate that responds well to corticosteroids.

33.17 PYRROLIZIDINE ALKALOID TOXICITY

Erwin G. Pearson

33.17.1 Definition and Etiology

Pyrrolizidine alkaloid (PA) toxicity is a chronic, progressive, often-delayed intoxication that results when animals consume plants containing PAs. The condition is manifested by signs of liver failure.[101] More than 350 PAs have been identified in over 6000 plant species.[102] Table 33-4 lists common plants containing PAs.

33.17.2 Clinical Signs and Differential Diagnosis

The clinical signs of PA poisoning are basically those of liver failure, as previously described under Diagnosis of Liver Disease. The most common signs of PA toxicity in the horse are weight loss, slight to moderate icterus, and abnormal behavior (e.g., wandering, ataxia).[103] Signs seen less frequently in horses include photosensitization of the white areas and, in rare cases, diarrhea. A few cases in ponies have shown loud,

stertorous inspiratory noises, possibly caused by pharyngeal-laryngeal paralysis.[7,104] We have seen pruritus in two cases involving horses, but never in cattle. Abortion may occur from ingestion of sublethal doses,[105] and PA has been shown to be teratogenic in rats.[106] Subtle signs such as poor performance (inability to race up to previous standards) may be seen in horses with pyrrolizidine-induced liver damage before the onset of liver failure. Secondary gastric impaction has been reported in ponies.[107]

Cattle more frequently show diarrhea, weight loss, tenesmus, prolapsed rectum, and ascites. Calves are much more susceptible than mature cattle. Behavioral changes or subtle neurologic signs may also be seen in cattle, but icterus is uncommon. Differential diagnosis includes other diseases causing liver failure (e.g., aflatoxicosis), as discussed in Chapter 54, and some chronic, debilitating diseases such as gastrointestinal parasites, liver flukes, and Johne's disease.[101]

Sheep and goats are more resistant to PA toxicosis but can be affected by certain alkaloids at doses 30 times or more the dose that affects cattle and horses. A consortium of ruminal microbes from sheep degrades PAs found in *Seneio jacobaea* to less toxic metabolites.[108] PA injected directly into the portal vein is toxic in sheep, as is *Senecio* when put in the abomasum.[109] Liver microsomal enzymes in sheep may also play a role in detoxifying PAs[110]; however, this alone does not seem to account for the differences in susceptibility.[111]

Table 33-4 Common Plants Containing Pyrrolizidine Alkaloids (PAs)

Botanical Name (Genus/Species)	Common Name
Senecio jacobaea	Tansy ragwort
Senecio vulgaris	Common groundsel
Senecio douglasii var. *longilobus*	Threadleaf groundsel
Senecio riddellii	Riddell groundsel
Senecio trianularis	Tarweed
Senecio alpinus	Alpenkreuzkraut (Europe)
Amsinckia intermedia	Fiddleneck
Crotalaria species	Rattlebox
Echium plantagineum, E. lycopsis	Viper's bugloss, Salvation Jane
Heliotropium europaeum	Common heliotrope
Symphytum officinale	Comfrey
Cynoglossum officinale	Hound's tongue (houndstongue)
Eupatorium maculatum	Bruner's trumpet
Baccharis pteronoides	Yerba de pasmo
Borago officinalis	Borage
Erechtites species	
Trichodesma species	

33.17.3 Clinical Pathology And Diagnostic Tests

The liver-derived serum enzyme activities are elevated during periods of active hepatocyte destruction caused by PA poisoning. Although the dehydrogenases (e.g., SDH, GLDH, LDH) are elevated initially, they may have returned to normal by the time the animal first shows clinical signs of functional failure. Because lesions are largely in the portal region, GGT and ALP tend to be consistently elevated.[112,113] In a study of sublethally poisoned horses, AST and the ratio of branched-chain/aromatic amino acids were persistently elevated.[105] Bile acids are increased and are increased early in some horses. Serum bile acid concentrations have a good predictive value, and levels above 50 μm/L would be a poor prognostic indicator in the horse.[114] Serum protein concentration is usually normal, and only terminally does albumin decrease or blood clotting become altered. Bilirubin, both direct and indirect, tends to be increased in the horse at the later stages of the disease process.

Liver biopsy is useful in arriving at a definitive diagnosis, but other causes of chronic hepatitis (e.g., aflatoxins) may produce a similar histologic appearance. The triad of fibrosis, bile duct proliferation, and megalocytosis is characteristic of PA toxicity. The histologic lesions are described more fully under Necropsy Findings. Some of the changes can be used for prognosis. Modest changes in the hepatocytes and biliary hyperplasia are reversible. Fibrosis bridging portal areas indicates an eventually fatal condition, as does the extensive fibrosis of an end-stage liver.

Feed samples can be examined for PA-containing plants. Cubed or pelleted feeds can be analyzed for PAs, but this is often time-consuming and relatively expensive.* A sulfur-bound pyrrolic metabolite was identified by thin-layer chromatography (TLC) on the hemoglobin of horses exposed to PAs.[115]

* AM Craig Laboratory, c/o VDL, Oregon State University, Corvallis, OR.

33.17.4 Pathophysiology

There are a number of PAs, and many of the poisonous plants contain four to six different alkaloids. About 50% of the alkaloids are toxic, and some are more toxic than others. The alkaloid concentrations vary slightly among plants from different areas, but there is greater variation in concentrations from different parts of the same plant.[116] After absorption the portal circulation carries the alkaloids to the liver, where they are metabolized by microsomal enzymes of the hepatocyte to more toxic pyrroles.[117] The pyrroles may cross-link double-strand DNA in a dose-dependent manner.[118] The degree of DNA cross-links depends on the concentration of the pyrrol, but not on the base sequence of the oligonucleotide target.[119] The cross-linking of DNA produces an antimitotic effect.[120] The hepatocytes cannot divide and often become megalocytes as cytoplasm expands without nuclear division. As cells die, they are replaced by connective tissue rather than new hepatocytes. This antimitotic effect may explain why megalocytosis (large hepatocytes and large nuclei) is seen with the disease. Besides cross-linking DNA, pyrroles, which are alkylating agents, may disrupt the hepatocyte in other ways.[121] They bind to protein and nucleic acid, thereby inhibiting enzymes and blocking protein synthesis. All these actions may lead to faster death of hepatocytes. With chronic doses, hepatocyte death is more severe in the portal areas (Rappaport zone 1), although some islands of necrosis do occur.[112,113] Centrilobular necrosis may be seen with massive doses.

With progressive death of hepatocytes and subsequent fibrosis, liver function begins to fail. The blood supply through the hepatic lobule is disrupted by fibrosis, making regeneration impossible. This becomes a

venoocclusive disease, resulting in marked portal hypertension. The increased portal hydrostatic pressure leads to diarrhea and ascites in ruminants. It is unclear why diarrhea and ascites are seen infrequently in horses with PA toxicity.

33.17.5 Epidemiology

PA toxicity is seen wherever plants containing the alkaloids are found. The plants are not very palatable and in most cases are not readily eaten, but animals may eat them when the growth of the toxic plant is so thick that the animal cannot separate it from normal forage, or when other forage is sparse. The plants are toxic in hay, including pelleted and cubed hay. Some herbicides may make the plants more palatable as they begin to die. PAs also survive ensilage; oat silage contaminated with *Amsinckia* or other PA-containing plants has been responsible for illness in dairy cattle. Seeds of *Heliotropium* plants have poisoned feedlot cattle.[122]

The approximate toxic dose of dried *Senecio* as a percentage of body weight for each species is horses, 5%; cattle, 2% to 5%; goats, 125% to 400%; and sheep, over 150%. Most tansy ragwort contains less than 0.2% PA by weight, but there are reports of much higher levels in some of the other plants.[123] Horses were consistently poisoned by greater than 250 mg of total PA per kg body weight.[114] The PA in hound's tongue is extremely toxic to horses.[124] This dose does not have to be eaten all at once, since the effects are cumulative. Because signs often are delayed, some animals may not become ill until a year or more after removal from feed sources containing the toxins.[113,125] Signs do not occur until hepatocyte loss and replacement by fibrous tissue have caused failure of liver function.

33.17.6 Necropsy Findings

Cattle dying of PA poisoning have ascites and prolapsed rectums and are thin and emaciated. Horses are usually thin and may be icteric. In all species the liver tends to be small, pale brown to yellow, and firm and may appear to be scarred. Hepatic megalocytosis is considered the hallmark of PA poisoning, but it has also been seen in aflatoxicosis and is not always apparent in the earliest stages of PA toxicity. Biliary hyperplasia may occur early in the disease. Nonspecific nuclear changes, such as invaginations of cytoplasm into the nucleus, have been seen.[112,113] Isolated hepatocyte necrosis is seen later, and finally, portal or massive generalized fibrosis develops. Once bridging of connective tissue between the portal areas occurs, the disease is fatal. The condition is called a "venoocclusive disease" because perivascular fibrosis sometimes occurs, but this is not a constant or characteristic feature.[126] Most of the vascular complications are caused by the generalized fibrosis and remodeling of the liver.

33.17.7 Prognosis

Liver failure may occur with either acute or chronic liver disease; the two must be differentiated for prognosis because end-stage fibrosis caused by PAs has virtually no chance for regeneration and recovery.

No satisfactory treatment for PA poisoning exists. Once obvious clinical signs of liver failure develop, the animal usually dies within 5 to 10 days. Horses with mild clinical signs and reversible histologic lesions survived if they retained an appetite and were not exposed to any more PA-contaminated feed.[105] An accurate prognosis concerning mildly affected cases may best be obtained from a combination of consecutive liver biopsies and liver-derived serum enzyme activity,[105] as well as from serum bile acid concentration.[114] Preventing further

exposure to the toxic plants is indicated and may delay or stop the progression of the liver lesions, particularly if an uncontaminated feed source is provided before clinical signs develop.

33.17.8 Treatment

Therapy of liver failure is inappropriate if severe fibrosis has occurred because regeneration is impossible. If the animal still has a reasonable appetite and only modest degrees of fibrosis histologically, treatment may be attempted by providing a low-protein, high-energy diet. The principles of treatment of hepatic disease should be followed (see p. 921).

33.17.9 Prevention and Control

PA poisoning is prevented by keeping susceptible animals from pasture, hay, cubed hay, or seeds that contains PA plants. *Senecio vulgaris* tends to contaminate mainly first-cutting alfalfa, whereas *Amsinckia intermedia* is often found in planted fields of oat hay. *Senecio* can be controlled by cultivation because it is a biennial, or by herbicide spraying in the early, rosette stage. Biologic controls for *Senecio jacobaea* include the cinnabar moth, *Tyria jacobae,* and the tansy flea beetle, *Longitarsus jacobae*. Sheep are sometimes used to graze *Senecio*-infested pastures to control the weed because they are less susceptible to the poisoning.

33.18 OTHER HEPATOTOXINS

Erwin G. Pearson

The liver is particularly vulnerable to toxic insults because it is the first organ to receive toxins absorbed from the GI tract. Enzymes in the hepatocyte may either activate a toxin or, in some cases, metabolize it before it can cause damage. Most hepatotoxic agents are described in more detail in Chapter 54. Some of the more common liver toxins are listed in Tables 33-5, 33-6, and 33-7, but these are not complete lists because many other plants and chemicals can damage the liver under the right conditions. Once a toxic liver disease has been diagnosed, possible sources of the toxin might be identified from these tables. A more detailed description of the toxin could then be found in Chapter 54.

33.19 LIVER FLUKES IN RUMINANTS

John B. Malone

The common liver fluke *Fasciola hepatica* causes a disease of production in ruminants that mimics the production effects and clinical appearance of the GI nematode-parasite complex. The disease often has its maximum economic effect in late fall and winter, when animals are most likely to be under seasonal nutritional stress. *F. hepatica* is unique among the common helminths of ruminants in that it has an asexual multiplication phase of the life cycle in snail intermediate hosts that is highly sensitive to environmental conditions. *F. hepatica* is well known for its exponential propagation of infective stages under favorable conditions, sometimes leading to explosive seasonal outbreaks of severe parasitism, especially in sheep. In addition, liver parenchyma migration forms leave necrotic tracts in their wake that are a primary predisposing factor in some areas for acute fatalities caused by *Clostridium novyi* (black disease) and *C. haemolyticum* (bacillary hemoglobinuria).[127]

33.19.1 Epidemiology

905

907

The geographic distribution of *F. hepatica* in the United States is limited mainly to areas in the south-central states and Florida and to the Pacific Northwest, where neutral, well-buffered soils are found and local hydrologic conditions provide suitable habitats for *Lymnaea* species, the snail intermediate hosts. The important vector species in temperate climates are semiaquatic "mud" snails found in disturbed mud banks and hoofprints in shallow depressions in fields, drainage channels, and temporary water bodies in alluvial river basins, bottomlands, and coastal regions of the southeastern United States. Springs, small streams, seeps, and sloughs serve as habitats in areas of greater terrain relief in the western states. Most infections occur by grazing in and around water in fluctuating habitats that stay wet for more than half the year.

Table 33-5 Hepatotoxic Plants

Common Name (Botanical Name)	Approximate LD_{50} (%BW)*	Geographic Distribution	Liver Lesion
For pyrrolizidine alkaloid—containing plants, see Table 33-4.			
Lantana *(Lantana camara)*	1	Northern North America	Necrosis, canalicular collapse
Rabbitbrush *(Tetradymia glabrata)*	0.5	Dry desert	Necrosis
Horsebrush (*Tetradymia* species)		Western U.S.	Necrosis
Sacahuista *(Nolina texana)*	1.1	Southwestern U.S.	Fatty and centrilobular necrosis
Lechuguilla *(Agave lecheguilla)*	4-15	Southern U.S., Mexico	Necrosis, photosensitivity
Puncture vine *(Tribulus terrestris)*	?	Warmer regions	Biliary fibrosis, necrosis (big head)
Whitebrush (*Lippa/Alosia* species)	?	Southern U.S., Mexico	Fatty degeneration
Panic grasses (*Panicum* species)	?	Texas-California, South America	Biliary fibrosis, necrosis
Kleunegrass *(Panicum coloratum)*	?	Southern U.S.	Necrosis, obstructed bile ducts
Bermudagrass *(Cynodon dactylon)*	?	North America	?
Cocklebur *(Xanthium orientale)*	0.75-3	North America	Hemorrhagic centrilobular necrosis
Lupine (*Lupinus* species) Mycotoxin from *Phornopsis inferior*	Varies	Western North America	Necrosis
Cottonseed (*Gossypium* species) Gossypol pigment	Varies; gossypol content	Southern U.S.	Necrosis Cardiac lesions
Poisonous mushrooms *(Amanita phalloides, Galerina veneta)*	Few mushrooms	North America	Necrosis Central nervous system signs
Blue-green algae *(Microcystis aeruginosa, Nodularia spumgena)*	? 0.001	Ponds, worldwide	Necrosis, dissociation
Alsike clover *(Trifolium hybridum)*	Varies	Cultivated	Portal fibrosis, biliary hyperplasia

Mexican fireweed *(Kochia scoparia)*	?	Southwest U.S. Central and South America	?
Cycad palm (*Cycas/Zamia* species)	?	South America, Australia	?
Yellow-wood *(Terminalia oblongata)*	?	Australia, Africa	Centrilobular necrosis
Sneezeweed (*Helenium* species)	0.25	Northern U.S., Canada	?
Moldy alfalfa *(Medicago sativa)*	?	Wet areas	Biliary hyperplasia, necrosis
Bitterweed (*Hymenoxys* species)	1	Southwestern U.S.	?

?, Unknown.

* Lethal dose (as percentage of body weight).

Table 33-6 Hepatotoxic Chemicals

Chemical	Source	Approximate Lethal Dose*	Liver Lesion
Carbon tetrachloride ($CC1_4$)	Tremacide	10-40 mg/kg	Fatty degeneration, centrilobular necrosis, cirrhosis
	Fumigant		
	Solvent		
C1-Hydrocarbons	Insecticides	Varies with species, chemical, and route	Necrosis
	PCBP		
	Solvents		
Pentachlorophenols	Wood preservative, herbicide, fungicide, molluscacide	100-200 mg/kg	Centrilobular fatty degeneration
Polybrominated biphenyl (PBB)	Fire retardant	100 mg/kg	Hemorrhagic necrosis, fatty degeneration
Carbon disulfide (CS_2)	Boticide	100 mg/kg	Necrosis
	Solvent		
	Fumigant		
Coal tar pitch	Clay pigeons	Swine 15 g/pig	Hemorrhagic necrosis
	Pipe sealer		
	Tar paper		
Phenol	Wood preservative	30 mg/kg	Hemorrhagic centrilobular necrosis
Iron	Iron supplements	>150 mg/kg young animals Older animals	Portal necrosis
	Injectable iron		
Copper	Species inappropriate supplements	Depends on species and molybdenum intake	Portal vacuolation and necrosis (hemolytic crisis)
	Fungicides, algicides		
	Molluscacide		
	Foot baths		
Phosphorus	Fertilizer	1-4 mg/kg	Portal necrosis and fatty degeneration
	Matches		

	Rodenticide		
Tannic acid	Oak	20 mg/kg	Centrilobular necrosis (also renal damage)
	Skin astringent		
Paraquat/diquat	Herbicide	4-10 mg/kg	Centrilobular necrosis (also lung damage)
Mycotoxins, aflatoxin B	Moldy feed	3 mg/kg	Centrilobular necrosis, biliary hyperplasia, megalocytosis
Rubratoxin B	Moldy feed	?	Necrosis
Sporidesmin	Moldy feed	?	Bile duct occlusion (big head)
Ochratoxin A	Moldy feed	?	Necrosis (also renal damage)
Phomopsin A	Lupine	?	Necrosis

?, Unknown.

* Lethal dose varies with individual, species, route of entry, rate or chronicity, enzyme induction, and many other factors.

Table 33-7 Drugs Used in Large Animals That Could Damage the Liver

Drug	Lesion*
Carbon tetrachloride	Centrilobular necrosis or fatty degeneration
Hexachloroethane	Centrilobular or massive necrosis
Carbon disulfide	Necrosis
Alcohol	Necrosis/cirrhosis
Tetracycline	Fatty degeneration (also renal damage)
Clindamycin	Cholestasis, icterus
Erythromycin	Cholestasis, icterus
Isoniazid	Active hepatitis → cirrhosis/massive necrosis
Rifampin	Cholestasis, icterus
Nitrofurantoin	Active hepatitis → cirrhosis
Anabolic steroids	Cholestasis, icterus
Phenothiazine	Cholestasis, icterus tranquilizers
Halothane	Active hepatitis → cirrhosis/massive necrosis
Fluothane	Active hepatitis/massive necrosis
Isoflurane	Active hepatitis/massive necrosis
Some diuretics	Cholestasis, icterus
Diazepam	Cholestasis, icterus
Phenobarbital	Necrosis/cholestasis icterus
Aspirin	Active hepatitis → cirrhosis
Oil of pennyroyal	Centrilobular necrosis
Tannic acid	Centrilobular necrosis, fatty degeneration (renal damage)
Dantrolene	Active hepatitis → cirrhosis
Copper disodiumedetate	Massive centrilobular necrosis
Iron (injectable)	Necrosis, portal, cirrhosis, hemosiderosis
Glucocorticoids	Hepatocellular vacuolization

* May vary with dose and time.

The life cycle development of both the snail host and the parasite in the snail occurs only when temperatures are above 10° C (50° F) and while snail habitats are wet. This leads to a distinct seasonal transmission in the mild, wet winter and spring of the south-central states and Florida and a late spring to fall transmission in the cooler climates of the western states (Figs. 33-1 and 33-2). It takes a minimum of 42 days at 25° C (77° F) or the accumulation of approximately 600 growing-degree days to complete intramolluscan development, with release of cercariae that encyst as infective metacercariae on pasture vegetation (600 growing-degree days = 25° C

minus the base temperature of 10° C = 15 growing-degree days × 42 days; an equivalent value for the life cycle is 15° C or 5 growing-degree days × 120 days). Using soil water budget analysis to indicate the length of time habitats are wet and the accumulated sum of growing-degree days over 600, a climate forecast index can be calculated for use in describing the pattern of seasonal transmission at a given site and to provide an indicator of the risk of economic losses in a given climate year. Two weeks of sustained summer heat and drought ends the transmission season by killing pasture metacercariae and forcing snail populations to estivate in soil or perish. In the cooler climates of the western United States, the season ends with drying of springs, seeps, sloughs, and other habitats or with the onset of sustained, cold winter weather. Variation in the annual climate alone may lead to a 100-fold variation in fluke burdens in different climate years (Table 33-8).[128]

907

908

Fig. 33-1 Pattern of *Fasciola hepatica* transmission typical of the southern United States (based on 10 years of experimental data from Alexandria, Louisiana) and strategic treatment recommendations with adulticidal drugs. From Malone JP et al: *Prev Vet Med* 3:131, 1985.

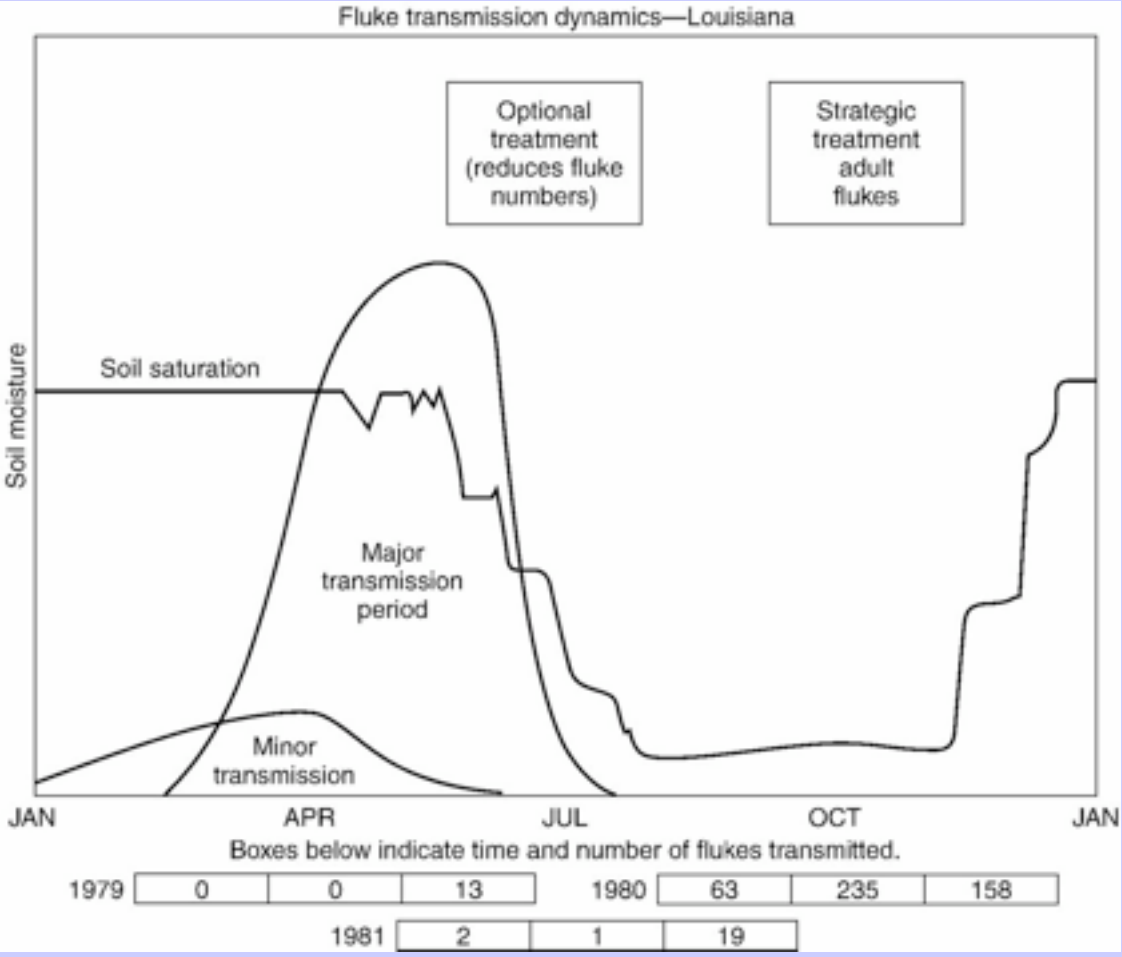

Fig. 33-2 Pattern of *Fasciola hepatica* transmission typical of the U.S. Pacific Northwest in natural rainfall and irrigated zones (based on experimental data from Langolis, Oregon) and strategic treatment recommendations with adulticidal drugs. From Rickard LG et al: *Vet Parasitol* 41:45, 1992.

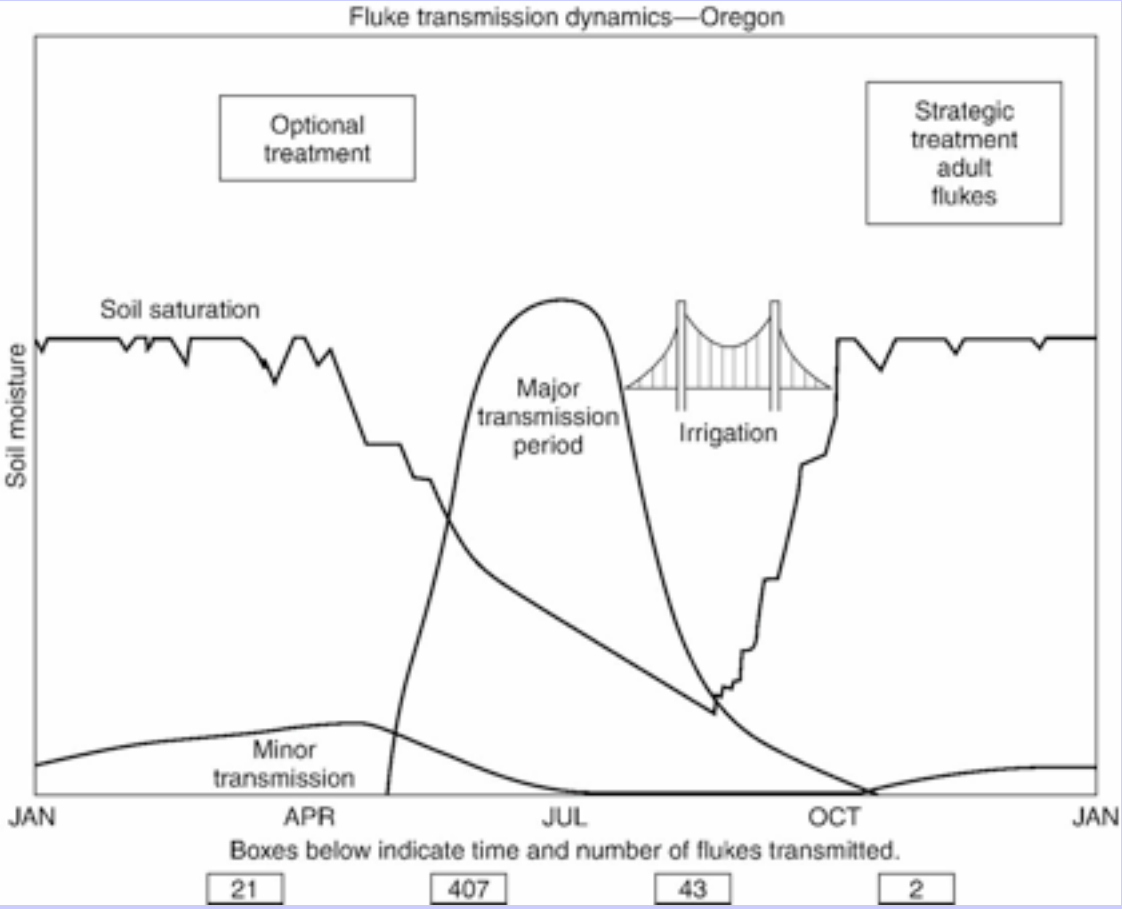

The amount of snail habitat present on individual farms related to pasture wetness conditions, such as premises with low-lying, heavy clay soils with a high water table, is also an important consideration in evaluating the need for fluke control. This factor has also been shown to lead to a 100-fold variation in the risk of fluke losses in the same year on different premises in otherwise ecologically similar areas.[129] The snail habitat area on most enzootic livestock operations typically is only 1% to 5% of the total land area; operations with over 5% habitat may be associated with a high risk of liver fluke losses.

908
909

Table 33-8 Spring and Autumn Forecast Index Values and Observed *Fasciola* risk at Dean Lee Research Station, Alexandria, Louisiana

Year	Spring Index	Autumn Index	Flukes per Calf	Risk
1979	416	1423	2	Low
1980	757	2949	75	High

Average†	1081	2385	110	

From Malone JB, Zukowski SH: *Parasitol Today* 8:266, 1992.

ND, Not determined.

* Average fluke number despite subterranean drainage of half of the farm and improved preventive herd treatment in 1983. The neighboring farm averaged 189 flukes per calf.

† The 30-year-average reference value computed by the model was 579 for spring and 1978 for autumn.

33.19.2

Clinical Signs and Pathophysiology

Subclinical production effects of *F. hepatica* include reduced rate of gain and feed efficiency in growing stock. Economic effects have been experimentally demonstrated in calves on a marginal nutritional plane in the first 5 to 6 months after infection, resulting in an 8% loss in the rate of gain with a mean of 40 flukes and a 28% loss with 140 flukes. In cattle it is estimated that herd economic losses are “negligible” with a burden of less than 10 flukes per animal, “possible” at 10 to 40 flukes, and “probable” with over 40 flukes; clinical disease is seen with a burden of more than 200 flukes. In cow-calf operations flukes often act in concert with periods of nutritional stress and concurrent heavy GI nematode infections, causing further reduction of body condition, poor milking ability, and slower return to estrus. This translates to reduced reproductive efficiency, prolonged calving interval, and lightweight calves at weaning.[130]

In cattle, flukes may lead to chronic disease or, in rare cases, subacute disease. When clinical signs occur, the typical population “overdispersion” (individual variation in parasite burdens) is manifested first in the 10% to 20% minority of the herd that harbor most of the parasite numbers. Signs may consist of weight loss, emaciation, depression, anorexia, rough hair coat, anemia, hypoproteinemia, submandibular edema, and, in rare cases, mild icterus. The anemia associated with *F. hepatica* infections is more than can be accounted for by blood feeding by

flukes. Evidence indicates that depression anemia and biliary hyperplasia result from high levels of proline, a product of fluke metabolism.[131] Cattle are able to mount a protective immune response, with partial acquired resistance to *F. hepatica,* beginning at 5 to 6 months after initial exposure.[132] This and the short lifespan of flukes in cattle typically lead to a linear reduction of fluke numbers, with few surviving by the end of 1 year. Sheep and goats are more susceptible, and fatal acute disease with ascites, abdominal hemorrhage, pallor, and icterus can occur in association with massive entry to the bile ducts at 6 to 10 weeks after infection by 1000 to 5000 or more migrating immature forms from the liver parenchyma. Subacute disease has been associated with a burden of more than 800 flukes acquired over time. Chronic clinical disease in sheep with submandibular edema, ascites, and emaciation has been associated with fluke burdens above 200.[133]

33.19.3 Necropsy Findings

Necropsy findings attributable to migrating young flukes are caused by tortuous tunnels of coagulative necrosis that organize and fibrose, ultimately leading to a diffusely fibrotic liver parenchyma, especially in the ventral lobe, which in severe cases undergoes marked atrophy. Fibrous tags may result from fibrinohemorrhagic deposits left by large numbers of flukes at liver penetration 3 to 4 days after infection. Inflammatory events associated with penetration of the bile ducts at 6 to 8 weeks after infection are especially pathogenic. Once in the bile ducts, flukes grow rapidly from 1 mm to 2.5 cm or more and induce a proliferative cholangiohepatitis. The spines and suckers of flukes erode and denude the bile duct epithelium, leading to a fibrosed, thickened duct wall that is irregularly dilated and stenotic and begins to calcify in cattle (but not sheep) at about 20 weeks after infection. The bile becomes darkly discolored and laden with regurgitated fluke ingesta, plasma proteins, and inflammatory cells. The extent of pathologic change is generally proportional to the fluke burdens of current or recurring previous infections.[133]

33.19.4 Diagnosis

Fecal sedimentation methods are the standard means of diagnosing liver flukes. A reusable commercial kit based on sieve-sedimentation of 2-g samples (Flukefinder, Visual Differences, Moscow, Idaho) reduces sample processing time by half and is suitable for use by practitioners for quantitative examination of an individual animal or of 10- to 15-animal herd composite samples. For herd or lot evaluations in cattle, egg counts of less than one egg per 2 g (EP2g) and 25% prevalence 2 to 4 months after the transmission season ends have a “low probability” of economic losses; 1 to 3 EP2g indicates “possible” economic loss; and 10 EP2g or more indicates “high probability” of heavy infections and economic loss. It is important to differentiate *F. hepatica* eggs from the eggs of *Paramphistomum* species, a nonpathogenic “rumen fluke” often found in the same herds in both the southern and the western enzootic areas. Flukecides used against *F. hepatica* are ineffective against rumen flukes, and egg counts thus persist after treatment. *Paramphistomum* eggs are gray (rather than amber), slightly smaller, and more pointed at the operculum end than *F. hepatica. Paramphistomum* egg counts can be used as a general indicator of the probable risk of *F. hepatica* in the absence of control in the southern states, because *Paramphistomum* flukes are known to be transmitted by the same snail vector in that region.[130]

Diagnostic enzyme-linked immunosorbent assays (ELISAs) have been developed to detect serum antibodies and coproantigen in the feces of infected animals[134] but have not yet found wide use outside of research or diagnostic laboratories. Blood and serum clinicopathologic results reflect the anemia, hypoproteinemia, and mild eosinophilia caused by *F. hepatica*. Pathologic changes in the liver bile ducts and parenchyma are reflected by an elevation in serum liver enzymes (e.g., GGT, GLDH).

33.19.5 Treatment and Control

Prevention is the key to control in foundation herds and flocks because even low numbers of eggs shed can multiply asexually in snails and lead to significant infection rates during the following transmission season. A single routine fall or late fall-winter treatment after the end of the transmission season with a highly effective drug is recommended to remove adult flukes before winter stress and to prevent egg shedding and snail infection in the next season (see Figs. 33-1 and 33-2). Most of the pathogenic and economic effects of flukes in cattle are reported to occur within the first 5 to 6 months after the major exposure period and may be related to metabolic products associated with the rapid growth and heavy egg production phases of the life cycle. This, coupled with linear loss of heavy fluke burdens in cattle and the onset of effective immunity at 20 weeks after exposure, suggests the value of early flukecide treatment, within 2 to 3 months after the transmission season ends. In some herds an optional curative treatment in spring may be needed in very high-risk years or on high-risk premises, or as a second treatment to remove flukes acquired during late, extended transmission on irrigation pastures or wet coastal areas in the west.

Flukecidal drugs available in the United States are effective against mature flukes in bile ducts (albendazole, 10 mg/kg; closulon, 2 mg/kg). Closulon at 7 mg/kg has added efficacy against juvenile flukes over 6 weeks old in the bile ducts. The optimum time to treat should be based on the estimated susceptibility of mature fluke populations (>12 weeks old after end of transmission season) but early enough to remove flukes while they are most pathogenic (<6 months old). Triclabendazole, which is widely used in other countries, is more than 90% effective against migrating flukes over 2 weeks old and 99% effective against mature flukes and can be effectively given just after transmission ends. Worldwide, a number of other drugs are available, including oxyclozanide, niclofolan, bithionol, and hexochlorophene (80% to 99% of adult flukes), nitroxanil, closantel (>90% adult and 50% to 90% juvenile bile duct flukes), rafoxinide (>50% late migratory flukes, >90% juvenile and adult bile duct flukes), and diamphenathide (>90% migratory flukes, 50% to 80% bile duct flukes).[135]

The economic benefit of routine flukecide treatment of feedlot calves from enzootic areas in the United States has not been consistently demonstrated industry-wide because of the high variability of fluke burdens in animals from enzootic areas, or because lots are often of mixed origin. Fluke-related losses would be expected to be mainly absorbed by stocker operations, where lightweight calves are typically placed on small grain pastures for extended periods before feedlot, a common practice in the south-central states. The economic return of treatment at feedlot should be evaluated on a case-by-case basis because significant losses may occur if the lot originates from the same premises and the history suggests a high risk of recent, heavy infection rates, such as in favorable climate years or use of irrigated pastures in fluke areas. Fecal egg counts on 10 to 15 randomly selected animals may aid in herd evaluation. An example case of the explosiveness of the life cycle is the greatly reduced feedlot performance and 100% liver condemnations of a lot from a stocker operation in the Pacific Northwest. The animals originated from irrigated pastures where some habitats stayed wet year-round, and untreated calves from fluke areas were allowed to contaminate pastures with eggs, which translated to infection later in the grazing season and to the next stocker group rotated onto the premises.

33.19.5.1 OTHER FLUKES

Fascioloides magna, the large American liver fluke, may infect cattle and sheep that graze common areas with deer, the natural host. The life cycle is similar to that of *Fasciola hepatica,* but with a wider variety of lymnaeid snail hosts and a broader geographic distribution in the Gulf States, the Great Lakes area, and the Northwest. Cattle are abnormal, dead-end hosts that react with an intense encapsulation response, forming a

closed cyst that does not allow escape of eggs and obviates diagnosis by fecal examination. The liver parenchyma and regional lymph nodes have a characteristic diffuse, black pigmentation. The major economic effect of *F. magna* in cattle is condemnation of livers and other organs, such as lungs, in which aberrant migration sometimes occurs. In sheep and goats, however, *F. magna* does not encyst and migrates uninterrupted. One or two *F. magna* flukes kill sheep before the flukes have time to mature, and this parasite limits sheep production in some areas. Albendazole given at high dosage is moderately effective against *F. magna*.

In tropical regions, *F. hepatica* is replaced by *Fasciola gigantica,* a similar species that is somewhat larger, has a longer prepatent period (10 to 12 weeks), and is of somewhat greater pathogenicity. *Dicrocoelium dendriticum* occurs worldwide but in North America is an unimportant species, mainly limited to areas of central New York, with smaller foci in Pennsylvania, New England, Quebec, and British Columbia. Albendazole (20 mg/kg) and high doses of thiabendazole (150 to 300 mg/kg) are effective treatments.[127]

33.20 HEPATIC ABSCESSES

T.G. Nagaraja

33.20.1 Definition and Etiology

Hepatic abscesses occur sporadically in most animals but are most common in ruminants, particularly cattle fed high-grain diets. Hepatic abscesses occur at all ages and in all types of cattle, including dairy cows, but have the greatest economic impact in feedlot cattle, in which the incidence ranges from 1% to 2% to as high as 90% to 95%, but averages 20% to 30% in most feedlots.[136] Because hepatic abscesses are generally a direct result of feeding practices, diet is an important factor influencing the prevalence. The prevalence of liver abscesses in dairy cows has not been documented, other than the anecdotal observations of liver abscesses “being not uncommon” in slaughtered heifers and cows. Most of the cows slaughtered are culled animals with low productivity, often related to disease, removed as a routine strategy to improve herd productivity.

Hepatic abscesses are generally polymicrobial infections, and in most cases the organisms are anaerobes. In the bovine, *Fusobacterium necrophorum* (formerly *Sphaerophorus necrophorus*), a gram-negative, pleomorphically rod-shaped anaerobe, is the primary etiologic agent. The organism also is implicated as the primary pathogen in necrotic laryngitis (calf diphtheria), foot rot, and foot abscesses in cattle.[137,138] *F. necrophorum* is a normal inhabitant of the rumen, and its role in ruminal fermentation is mainly to utilize lactic acid and degrade protein. The organism is in higher concentration in grain-fed than forage-fed cattle, possibly because of the increased availability of lactic acid from starch fermentation. Several virulence factors have been implicated in the pathogenesis of *F. necrophorum* infections.[138] These include leukotoxin, endotoxic lipopolysaccharide (LPS), hemolysin, hemagglutinin, capsule, adhesins or pili, platelet aggregation factor, dermonecrotic toxin, and extracellular enzymes (e.g., proteases, deoxyribonucleases).[139] Leukotoxin is believed to be the major virulence factor. The leukotoxin is cytotoxic to polymorphonuclear neutrophil leukocytes (PMNs), macrophages, hepatocytes, and ruminal epithelial cells. Because of leukotoxin, the organism is able to survive, proliferate, and establish itself, to set up infection of the ruminal wall and liver. There are two subspecies of *F. necrophorum,* subsp. *necrophorum* (formerly biotype A) and subsp. *funduliforme* (formerly biotype B). These two subspecies differ in cell morphology, colony characteristics, growth patterns in broth, and most importantly, in virulence factors. Subspecies *necrophorum* is more virulent (produces more leukotoxin) and thus more frequently encountered in liver abscesses than subsp. *funduliforme,* which tends to occur more often in mixed infections.[140,141]

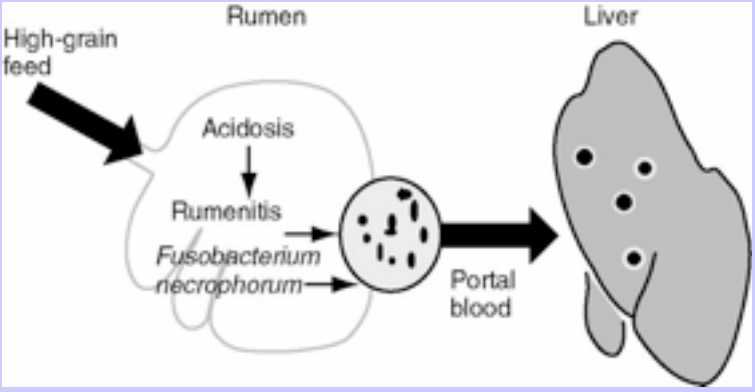
In most situations, *Arcanobacterium pyogenes* (formerly *Actinomyces, Corynebacterium*), a gram-positive rod shaped organism, is the second most frequent pathogen isolated from liver abscesses. The ruminal wall appears to be the niche for *A. pyogenes,* an aerobe, because the wall provides an aerobic microenvironment in an otherwise anaerobic environment of the rumen.[142] The organism may also act in synergy with *F. necrophorum* to cause liver abscesses.[143]

33.20.2 Pathogenesis

Abscesses in the liver result from entry and establishment of *F. necrophorum* either alone or with other bacteria. The routes by which the bacteria can gain access to the liver include: the portal vein, hepatic artery, umbilical vein (in newborn with omphalophlebitis), bile duct system, and direct extension. Entry through the hepatic artery (after an episode of septicemia) or the bile ducts (usually from obstruction, infection ascending from duodenum, or migration of flukes) is a rare occurrence. The direct extension of infection from adjacent tissues and organs, usually of traumatic origin, such as direct puncture of the liver by a foreign body lodged in the reticulum, is more likely to occur in dairy cows. Traumatic reticuloperitonitis caused by metallic objects lodged in the reticulum and perforating through the reticular wall, rarely involving the ruminal wall, is often a predisposing factor for liver abscesses in dairy cows. However, in both dairy cows and feedlot cattle, the most common route of entry of bacteria into the liver is the portal vein.

Liver abscesses are secondary to the primary foci of infection in the ruminal wall. Evidence to support this is the high correlation between ruminal wall lesions (rumenitis) and liver abscesses, thus the term *rumenitis—liver abscess complex* (Fig. 33-3). It is well accepted that ruminal lesions resulting from acidosis are the predisposing factors for hepatic abscesses. Acid-induced rumenitis and damage of the protective surface usually are associated with a sudden change to high-energy diets and other dietary indiscretions, such as a change in feeding patterns, letting cattle become overly hungry, feeding unpalatable diets, and feeding very little roughage.[144] The ruminal damage often is aggravated by foreign objects in the feed, sharp feed particles, or hair.[143] The ruminal wall that is damaged from acidity or penetration of foreign objects becomes susceptible to invasion and colonization by *F. necrophorum*. Once colonization has occurred, *F. necrophorum* can gain entry into the blood or cause ruminal wall abscesses and subsequently shed bacterial emboli to the portal circulation. Bacteria from the portal circulation are filtered by the liver, leading to infection and abscess formation.

Fig. 33-3 Pathogenesis of liver abscesses in cattle fed high-grain diets. Modified from Nagaraja TJ, Chengappa MM: *J Anim Sci* 76:287, 1998.



Undoubtedly, the virulence factors of *F. necrophorum* play a critical role in the penetration and colonization of the ruminal epithelium and entry and establishment of infection in the liver. The protease activity, dermonecrotic activity, and cytotoxic effect of leukotoxin on ruminal cells may aid in penetration and colonization of the ruminal wall. *F. necrophorum*, being an anaerobe, must overcome both high oxygen concentrations and phagocytic mechanisms to survive, proliferate, and initiate abscess formation. The leukotoxin may protect it from phagocytosis. Also, the release of cytolytic products such as lysosomal enzymes and oxygen metabolites, resulting from destruction of phagocytes, has a detrimental effect on the liver parenchyma. Synergism with facultative bacteria, intravascular coagulation induced by endotoxic LPS and platelet aggregation factor; formation of fibrin-encapsulated abscesses, and impairment of oxygen transport by damaged erythrocytes (action of hemolysin) all may contribute to the establishment of an anaerobic microenvironment conducive to the growth of anaerobic bacteria within the ruminal wall and liver.

33.20.3 Pathology

Abscesses found in the liver at slaughter or necropsy often are well encapsulated, possessing thick, fibrotic walls. Histologically, a typical abscess is pyogranulomatous, with a necrotic center, encapsulated, and often surrounded by an inflammatory zone.[141] Hepatic abscesses are pus filled, have capsules that vary in thickness, and range in size from a minute pinpoint to over 15 cm (6 inches) in diameter. The number of abscesses in the liver can vary from one to hundreds, and sizes range from less than 1 cm (0.4 inch) to greater than 15 cm in diameter, often encircled by a hyperemic zone. The larger abscesses may be the result of small abscesses coalescing early in development. The distribution of abscesses in the liver shows no consistent pattern, with superficial and deep abscesses distributed almost evenly. Often, small abscesses are scattered throughout the organ, whereas large abscesses are located close to the portal entry.

33.20.4 Clinical Signs and Diagnosis

Liver abscesses are detected only at the time of slaughter. Cattle, even those that carry hundreds of small abscesses or several large abscesses, seldom show any clinical signs. Occasionally, the rupture of a superficial abscess or erosion and perforation of the caudal vena cava could lead to extensive spread and massive infection of other organs and eventual death. Generally, hematology and liver function tests have not proved to be good indicators of liver abscesses.[145] In animals in which abscesses were induced by experimental inoculation of *F. necrophorum,* hepatic dysfunction was documented by elevated serum protein, bilirubin, and enzymes, such as GGT and SDH concentrations.[146]

Ultrasonography is a useful technique in the diagnosis of various hepatic diseases in cattle because of the location and tissue consistency of the liver.[147] The technique has been shown to be useful for monitoring the onset and progression of experimentally induced abscesses where the site of injection is known.[146] The development of abscesses in feedlot calves has been recorded by ultrsonographic examination at regular intervals from weaning to slaughter.[145] However, its application to the diagnosis in feedlot cattle is limited because the ultrasonographic scanning cannot visualize the whole liver, particularly the left side facing the internal organs, and parts of lobes are covered by other organs (e.g., lungs, kidneys).

33.20.5 Treatment

911

912

Both *F. necrophorum* and *A. pyogenes* are susceptible to penicillins and macrolides. However, antibiotic treatment is seldom practical in cattle because complete recovery is difficult to attain. Cattle with sequelae (e.g., CVCT syndrome), for economic reasons, are generally culled for slaughter.

33.20.6 Prevention

According to the U.S. *Feed Additive Compendium,* five antibiotics (bacitracin methylene disalicylate, chlortetracycline, oxytetracycline, tylosin, and virginiamycin) are approved for prevention of liver abscesses in feedlot cattle.[148] These antibiotics vary in their inhibitory effect on *F. necrophorum* and *A. pyogenes* and their effectiveness in preventing liver abscesses. Tylosin, a macrolide, is the most effective antibiotic and the most commonly used feed additive (6 to 8 g/ton, or 60 to 90 mg/head/day) in the feedlot. Studies show that tylosin feeding reduces abscess incidence about 40% to 70%. A vaccine combination of *F. necrophorum* leukotoxoid and *A. pyogenes* bacterin given to feedlot cattle has been shown to reduce the prevalence and severity of liver abscesses.[149] In addition to inclusion of antimicrobial compounds in the feed or vaccination, prudent bunk management to minimize ruminal acidosis is well accepted as a key factor for effective control of liver abscesses.

33.20.6.1 SEQUELAE

Septic cardiac and pulmonary emboli are also associated with liver abscesses in feedlot and dairy cattle. Occasionally, sudden death has been reported in cattle secondary to rupture of liver abscesses, with septic embolization in the right side of the heart. Generally, the condition starts as phlebitis caused by the extension of liver abscesses involving caudal vena cava. The phlebitis leads to thrombus formation anywhere between the liver and right atrium, but most often at the point of entry of caudal vena cava into the diaphragm. The clinical syndrome and the extent of lesions observed depend on the degree of thrombosis and type of organisms involved. The syndrome can range from death caused by rupture of caudal vena cava to various degrees of pulmonary embolism, pneumonia, infarction, endocarditis, hemoptysis, and epistaxis. Collectively, these lesions are categorized under *caudal vena cava thrombosis* (CVCT) *syndrome*.[150,151]

33.20.6.2 ECONOMIC IMPORTANCE

Liver abscesses are a major economic liability to the producer, the packer, and ultimately the consumer of beef. Abscesses are the leading cause of liver condemnation in the United States. The National Beef Quality Audit indicated that liver condemnations ranked as one of the top-10 concerns of packers.[152] The greatest economic impact of hepatic abscesses is not from the condemnation of liver but from the reduced animal performance. Cattle with abscessed livers have reduced feed intake, reduced weight gain, decreased feed efficiency, and decreased carcass dressing percentage. These effects are evident only in cattle with the most severe abscesses (one or more large abscesses or multiple small abscesses).[153]

33.20.6.3 HEPATIC ABSCESSES IN HORSES

Hepatic abscesses occur sporadically in horses and are generally part of the intraabdominal abscess complex. In studies that have evaluated horses with intraabdominal abscesses, 12% (3/25)[154] and 53% (8/15)[155] of horses had abscesses in the liver. Hepatic abscesses in horses are usually associated with septic portal vein thrombosis but may also develop as an extension of the inflammatory process involving the intestinal tract, or as sequelae to abdominal surgery.[156] A variety of bacterial species, particularly anaerobes, have been cultured from the pus. The most frequently isolated bacteria include *Streptococcus equi, Escherichia coli, Bacteroides fragilis, Corynebacterium pseudotuberculosis, Fusobacterium necrophorum,* and *Peptostreptococcus* species.[155–157]

Clinically, horses with hepatic abscesses cannot be differentiated from other intraabdominal abscesses. Generally, horses have a history of fever, loss of appetite, signs of colic, depression, and weight loss. Clinicopathologic changes are typical of chronic bacterial infection and include leukocytosis, thrombocytosis, hypoalbulinemia and decreased A/G ratio.[154–156] The prognosis is generally poor because of failure to respond to antimicrobial treatment. Percutaneous or surgical drainage has been shown to be effective, with high survival rate in humans with hepatic abscesses.

33.21 HEPATIC LIPIDOSIS

John Maas

Erwin G. Pearson

The conditions described next can cause hepatic lipidosis. Pathophysiology and prevention are similar for each and are described at the end of this section.

33.22 FAT COW SYNDROME, LIPID MOBILIZATION SYNDROME

33.22.1 Definition and Etiology

Fat cow syndrome is a multifactorial condition occurring in dairy cows after parturition. The syndrome is characterized by progressive depression and failure to respond to treatment of other predisposing diseases. It is associated with excessive mobilization of fat to the liver in well-conditioned or overconditioned cows. This mobilization of fat is induced by the negative energy balance and hormonal changes that occur during the periparturient period. This negative energy balance in most cases is aggravated by concurrent periparturient diseases that reduce feed intake and increase energy needs.[158–161]

33.22.2 Clinical Signs

The clinical condition occurs in the postparturient period. Most affected cows are either obese or very well conditioned, with a large amount of omental and subcutaneous fat. Presenting signs usually include depression, anorexia, weight loss, and weakness that can lead to recumbency. Most will have nonspecific signs, such as decreased rumen motility and decreased milk production. Other signs vary and are related to concurrent diseases. The concurrent diseases most frequently seen are metritis, retained fetal membranes, mastitis, parturient paresis,

and displaced abomasum.[158,159] It is important to look for these other diseases; even if mild, they could be significant in these cases and must be treated.

33.22.3 Clinical Pathology and Diagnostic Tests

Most laboratory tests are poor indicators of hepatic lipidosis and are of little value in determining the severity of the disease.[162] Liver-derived enzymes are usually elevated above the level in the dry cow but are often within normal ranges. Some serum enzyme levels increase in the periparturient period in normal cows. Many cows with hepatic lipidosis have a leukopenia and a degenerative left shift, but this is not specific. As expected, serum free fatty acids (FFAs) will be increased, and triglycerides and cholesterol will be decreased. Most of the total cholesterol is in lipoproteins. Serum total bile acids are not significantly increased in most cows with fatty livers.[163] The sulfobromophthalein dye excretion test may be useful prognostically, because those with a half-life longer than 9 minutes have a more guarded prognosis.[164] Table 33-9 provides common abnormal laboratory findings.

912

913

Table 33-9 Common Clinicopathologic Abnormalities in Fat Cow Syndrome

Test Parameter	Change from Normal	Amount	Normal (X ± 2 SD)	
			Prepartum Dry	Postpartum (1-2 wk)
Ketonuria	↑	>(1+)	0	Trace +
FFA (μEq/L)	↑	>800	343-575	597-821
Triglycerides (mg/dL)	↓	<5	—	—
BUN (mg/dL)	↑ or Normal	>20	16-24	16-24
BSP clearance T½ min	↑	<5	4.4-4.8	4.7-5.5
GGT (IU/L)	↑	>16	44-56	65-78
AST (IU/L)	↑	>70	44-56	65-78
Insulin (U/mL)	↓ Variable	—	12-17	6.8-9.2
Glucose (mg/dL)	↓	—	52-57	48-52
White blood cells	↓	<4000 Neutrophils > lymphocytes	4000-12000 Neutrophils < lymphocytes	—

FFA, Free fatty acids; *BUN,* blood urea nitrogen; *BSP,* Bromsulphalein (sulfobromophthalein); *GGT,* γ-glutamyltransferase.

Liver biopsy may confirm the fatty infiltration of the hepatocytes, but a moderate to high amount of fat (15% to 30% total fat on a wet-weight basis)* is present in the liver of all postparturient, high-producing dairy cows, even those that remain healthy.[165,166] Fat is usually quantified by histologic methods, by measuring total hepatic fat on a wet weight basis, or by floating in copper sulfate solutions of various specific gravity (to estimate total fat

on a wet-weight basis).[167] A recent review advocated the use of tricacylglycerol analysis on a wet-weight basis to differentiate degrees of hepatic lipidosis.[161] These workers categorized hepatic lipidosis as normal, mild, moderate, and severe by the triacylglycerol concentrations of less than 1%, 1% to 5%, 5% to 10%, and greater than 10%, respectively.[161] At present, triacylglycerol analysis of hepatic tissue is not a routine procedure in veterinary diagnostic laboratories. Thus, total hepatic fat concentrations remain the "gold standard" for laboratory diagnosis. Clinically, little correlation exists between the amount of hepatic fat and signs of disease until the fat is more than 34% wet weight, at which point the liver tissue will float in distilled water with a specific gravity of 1.000.

* Extraction by solvent and stereologic postcounting for estimation of fat volume.

33.22.4 Pathophysiology

See pp. 915 and 916.

33.22.5 Epidemiology

Fat cow syndrome occurs sporadically in dairy cows but more frequently in those with loose housing where the dry cows are managed with the lactating cows in one group. Cows often become overconditioned during late lactation and during the dry period. The overconditioning may be caused by a poor breeding program associated with cows spending prolonged time in the low lactation strings and having excessive weight gain. Morbidity as high as 90% occurred in the original reports.[160] Mortality can exceed 25%, with even higher rates without intensive treatment and correction of concurrent diseases. Clinical disease in obese cows that enter the dry period can be minimized by carefully controlling their diets to meet National Research Council (NRC) requirements and preventing milk fever.

33.22.6 Necropsy Findings

Generalized obesity is noted unless the animal has been ill for more than 1 to 2 weeks. Changes in the liver are most striking; it is enlarged, with swollen and rounded edges, is pale yellow in color, and may float in water. Histologically, there is fatty infiltration of the hepatocytes, especially in the centrilobular and intermediate areas. However, these liver tissues are not much different from those of healthy, high-producing dairy cows in early lactation. The pathologist must make an extra effort to find lesions of other periparturient diseases, even if mild.

33.22.7 Treatment and Prognosis

Prognosis must be guarded unless the concurrent diseases can be treated successfully and the liver fat mobilized. It is most important to treat the primary disease. Reducing the negative energy balance and treating the hepatic lipidosis as described on p. 916 must be tackled vigorously. Prevention is based on preventing overconditioning during the late lactation period and the dry period and treating periparturient diseases in a timely manner. General prevention of hepatic lipidosis is covered in more detail on p. 917.

33.23 PROTEIN-ENERGY MALNUTRITION/PREGNANCY TOXEMIA OF BEEF COWS

33.23.1 Etiology

Protein-energy malnutrition (PEM) and pregnancy toxemia of beef cows are conditions of pregnant beef cattle on marginal diets, usually occurring in the winter and manifested by weight loss, weakness, depression, and sometimes inability to rise. The condition is the result of the negative energy balance caused by decreased quality and quantity of feed when caloric requirements are increased by fetal development and cold weather. Growing, pregnant heifers are especially susceptible because energy requirements for growth are superimposed on the other caloric requirements. A number of other factors, such as unpalatable feed, snow cover, and diseases, may reduce caloric intake (see Chapter 9). Fatty infiltration of hepatocytes occurs transiently in early PEM, and at necropsy the liver is smaller than normal.

33.23.2 Clinical Signs and Differential Diagnosis

Animals are usually thin and have a long hair coat. In some cases they are down and unable to rise but are still alert. The body temperature may be normal or subnormal. Occasionally, the cows also develop diarrhea. Most animals die 7 to 14 days after becoming recumbent.[168] Differential diagnosis includes Johne's disease, lymphosarcoma, parasitism, chronic pulmonary disease, other deficiencies, and debilitating diseases.

913

914

33.23.3 Clinical Pathology and Diagnostic Tests

Diagnosis is usually based on demonstrating decreased caloric intake and ruling out other chronic diseases that could cause debility. Laboratory tests support but do not rule out the disease. Total serum calcium may be decreased. Packed cell volume also may be decreased, and serum insulin levels may be reduced. A ketonuria is not typical in PEM.

33.23.4 Necropsy Findings

Muscle mass usually is decreased. Serous (brown) atrophy of fat is often present, especially in the coronary groove, bone marrow, and perirenal areas. Lesions of concurrent disease also may be found if PEM is acute, and a fatty yellow liver may be noted.

33.23.5 Treatment and Prognosis

Treatment is often unrewarding. Efforts to reverse an advanced catabolic state may fail. A 454-kg cow requires 13 Mcal of metabolizable energy daily, or approximately 6.5 L of 50% glucose solution by continuous drip. Alfalfa pellet gruels are helpful if force-fed, and approximately 11 kg/day of alfalfa is recommended. Propylene glycol (150 to 200 mL) orally twice daily can be helpful as a glucose precursor. Treatments include IV fluids, improving the energy balance as described later, and treating any concurrent disease. Prevention and control by nutrition are discussed on p. 917.

33.24 PREGNANCY TOXEMIA IN EWES AND DOES

33.24.1 Definition and Etiology

Pregnancy toxemia, also known as ketosis or twin-lamb disease, is a condition occurring in ewes and does during the last 2 to 4 weeks of gestation. It is characterized by anorexia, weakness, and depression. The condition is caused by a negative energy balance resulting from increased energy demands of rapid fetal growth in late gestation and insufficient intake.

33.24.2 Clinical Signs

Animals with pregnancy toxemia are usually separated from the rest of the flock or herd. They have a poor appetite, and many appear blind. They eventually become more depressed and recumbent. Neurologic signs such as tremors, star-gazing, incoordination, circling, and grinding the teeth may precede terminal depression. Differential diagnosis includes other periparturient diseases, such as mastitis and hypocalcemia, as well as polioencephalomalacia, enterotoxemia type D, and toxicoses.

33.24.3 Clinical Pathology and Diagnostic Tests

Ketonuria is usually present and detected before ketonemia. Hypoglycemia is not a consistent finding but is sometimes present. The ewes and does often are acidotic and may have lowered serum calcium and potassium levels. The BUN and creatine levels are elevated terminally in some cases. FFA concentration in the plasma is usually elevated above 500 μEq/L. Serum β-hydroxybutyrate concentrations are elevated (>1 mmol/L).[169] A nonspecific but marked neutrophilia may be found in some affected animals and is particularly dramatic in does, sometimes reaching 35,000 neutrophils/μL.

33.24.4 Pathophysiology

See p. 915.

33.24.5 Epidemiology

The incidence of pregnancy toxemia is greater in ewes with more than one fetus, during the last 2 to 4 weeks of gestation,[170] and in does with three or more fetuses. Poor-quality feed, cold weather, lack of exercise, and stress of movement also may increase the incidence. Many ewes are overly fat initially. Does seem to be more resistant to pregnancy toxemia than ewes, in that three or more fetuses are usually required to produce the condition.

33.24.6 Necropsy Findings

These animals have a pale, swollen, friable, fatty liver. The animals may be somewhat dehydrated, and the uterus usually has more than one fetus.

33.24.7 Prognosis and Treatment

Mortality is high unless treatment is started early and the fetuses are removed. The most important step is removing the fetuses, either by inducing parturition or by cesarean section. Parturition can be induced in ewes with 15 to 20 mg of dexamethasone; in does the dose is either 10 mg of dexamethasone or 10 μg of prostaglandin $F_{2\alpha}$.[170] A cesarean section may be performed if the animal's value warrants it and there does not seem to be enough time to induce parturition. Besides removing the fetuses, the ketotic condition should be treated; 250 to 500 mL of 10% to 20% glucose is given intravenously, followed by a slow IV drip of 5% to 10% glucose. Acidosis and hypocalcemia must be corrected if present. Many practitioners use B vitamins in an attempt to stimulate appetite. Transfaunation of rumen liquor from a normal ruminant (a cow is acceptable) is useful in promoting voluntary feed intake and rumen motility. Cyanocobalamin (vitamin B_{12}) and biotin are particularly indicated as adjuncts to glucogenesis. The energy intake must be increased. Glucose precursors such as propylene glycol (15 to 30 mL every 12 hours) or sodium propionate are often used, but excess propylene glycol may lead to acidosis and cause diarrhea.

33.25 HYPERLIPEMIA/HYPERLIPIDEMIA IN PONIES

33.25.1 Definition and Etiology

Hyperlipemia occurs mainly in ponies and occasionally in horses and is characterized by a fatty liver and serum that is cloudy with accumulation of lipids. Triglycerides (TGs) are usually much higher than 500 mg/dL.[171] The condition is caused by decreased caloric intake, which causes fat mobilization and fat accumulation in the liver and accumulation in the plasma.[172] The decreased food intake may be secondary to other diseases. In horses, azotemia is usually also present and may block further TG uptake by the liver.[171] Equine hyperlipemia is characterized by production of an abnormal very-low-density lipoprotein (VLDL) fraction ($VLDL_1$), which has a reduced content of apolipoprotein B-100 and an increased content of apolipoprotein B-48.[173] The substitution of B-48 for B-100 is thought to allow greater TG content because B-48 is the apolipoprotein of importance in chylomicrons. The activities of lipoprotein lipase and hepatic lipase, the enzymes responsible for VLDL catabolism, were increased in hyperlipemic ponies.[173] It was concluded that overproduction of VLDL is the cause of hyperlipemia, and agents that reduce VLDL synthesis should be candidates for clinical investigation.[173]

Hyperlipidemia is a mild condition of ponies and horses characterized by mildly elevated TG concentrations (>500 mg/dL), clear plasma, and no evidence of hepatic dysfunction.[171] An increase in caloric intake is usually sufficient to reverse the condition. The more severe condition, hyperlipemia, is discussed further.

914

915

33.25.2 Clinical Signs

The clinical signs of hyperlipemia are not specific. Ponies usually are anorexic, depressed, weak, and incoordinated. Diarrhea is a common clinical sign.[174]

33.25.3 Clinical Pathology and Diagnostic Tests

Diagnosis is based on examination of the blood and plasma to detect the white to yellow opacity caused by the presence of lipids. Bilirubin usually is elevated, as in most horses that are fasted. TGs are increased to above 500 mg/dL in hyperlipemia. FFAs are also increased. Bromosulfophthalein clearances are delayed (see p. 897), and terminally a large base deficit may be caused by metabolic acidosis.[171]

33.25.4 Epidemiology

The incidence of hyperlipemia is greater in ponies than in horses. It is seen more often in the winter, especially from February to May in animals receiving poor feed. Pregnant animals and those that are lactating are affected more frequently.

33.25.5 Necropsy Findings

Postmortem examination reveals fatty infiltration of the liver and kidneys, which are pale and swollen and have a greasy texture. In ponies the liver is sometimes ruptured, resulting in intraabdominal hemorrhage and death. Renal lesions may be seen histologically. There may be a primary disease that produces anorexia and secondarily has resulted in hyperlipemia.

33.25.6 Treatment

It is most important to treat any primary disease to alleviate the cause of anorexia and to correct the negative energy balance, as described in the following paragraphs. Insulin, along with 100 g of glucose intravenously, has been used in some affected ponies.[174] The recommended dose of protamine zinc insulin (PZI)* is 30 IU intramuscularly twice daily with 100 g of glucose orally for a 200-kg pony. This is continued on odd days; on even days, 15 IU of PZI intramuscularly and 100 g of galactose orally is given twice daily.[171] A slow IV drip of glucose for several days or until lipemia clears may be indicated. Heparin (100 to 250 IU/kg twice daily) has been used to alter the lipoprotein lipase activity and inhibit hormone-sensitive lipase of adipose tissue, but it may alter coagulation enough to cause hemorrhage. Glucose administration also stimulates insulin levels, but overdoses may result in a more severe acidosis.[123]

* Protamine zinc and iletin insulin, Lilly, Indianapolis, IN.

33.25.7 Pathophysiology of Hepatic Lipidoses(Fig. 33-4)

Storage of excess energy as fat and the periodic mobilization of fat for use as energy by the body is crucial.[175] The liver plays a major role in lipid metabolism and must process the absorbed chylomicrons, the volatile fatty acids, and many of the FFAs and much of the glycerol obtained by mobilization of fat from adipose tissue. The liver of large herbivores has unique functions because much of the dietary energy is absorbed as volatile fatty acids and not glucose. Glucose is still needed (in high amounts in lactating animals) and must be produced by gluconeogenesis, 85% of which takes place in the liver.[176]

Negative energy balance is induced by lactation, fetal growth, exercise, decreased feed consumption, environmental chilling, and diseases (Fig. 33-5). During these periods of negative energy balance and before

lactation, blood glucose may drop slightly, the insulin/glucagon ratio drops, and these and other hormones (e.g., catecholamines, growth hormone) activate hormone-sensitive lipases that convert tissue fat to FFAs or nonesterified fatty acids (NEFAs) and glycerol (Fig. 33-6). In the liver the glycerol may be used to produce glucose or may be recombined with FFAs to make TGs. In addition to being recombined with glycerol to make TGs, the FFAs may be degraded through β-oxidation, and the two carbon fatty acids converted to acetyl coenzyme A (CoA). The acetyl CoA combines with oxaloacetate to enter the tricarboxylic acid cycle for the production of energy. This pathway is in competition with the use of oxaloacetate for gluconeogenesis.[159] If there is not enough oxaloacetate available, the acetyl CoA is converted to ketone bodies, which in high concentrations can reduce feed consumption and perpetuate the negative energy balance.

When the liver is overwhelmed with mobilized FFAs, greater amounts of TGs are deposited within the hepatocytes. These TGs eventually leave the liver as VLDLs, which are plasma-soluble complexes of phospholipid, cholesterol, TG, and apolipoprotein A. Hepatic lipidosis results when the rate of hepatic TG formation exceeds oxidation of fatty acids and the formation and release of VLDLs into the peripheral circulation. A number of factors have been incriminated for the inability of the liver to secrete adequate VLDLs to keep up with the deposition of TGs brought about by FFA mobilization from fat. Ruminants have a poor ability to export excess lipid from the liver as VLDLs. This is particularly true in bovine hepatic lipidosis[177,178] and is theorized to result from a shortage of apolipoprotein A. Hepatic lipidosis can be induced in cows by inhibiting the production of apolipoprotein,[179] and the lowest concentrations of lipoproteins occur in the serum of cows with the most severe hepatic lipidosis.[178] Cows on low-protein diets in the dry period are more likely to develop hepatic lipidosis than those on higher protein diets, regardless of the energy content.[177,180] Depression in dry matter intake in the final week before calving will increase the liver TG content after calving in dairy cows.[181] In the past, a lack of phospholipid or its precursor choline has been incriminated but never substantiated. However, in the face of an energy shortage, it seems redundant and a waste of energy to repackage fat and send it back to the tissues, even if the liver is being overwhelmed with FFAs. Some of the same endocrine hormones that activate hormone-sensitive lipase and inhibit lipogenesis and glycogen synthesis may also inhibit the production of VLDLs.

It has also been suggested that subclinical liver damage may inhibit the production of VLDLs, but experimental studies have indicated no significant elevation in liver-specific enzymes before lipid accumulation.[165,166] Function may eventually be impaired by the accumulation of fat, because fasted cows have a decrease in the surface area of rough endoplasmic reticulum and the number of mitochondria per unit volume.[182] Changes in the liver seem to be functional and not degenerative.[183] Hepatic lipidosis appears to be a reversible condition if the cause is removed and energy balance becomes positive (less negative). In cows fasted and refed, all major liver functions returned to normal within 18 days of refeeding,[182] and all lactating dairy cows with postparturient hepatic lipidosis had normal liver fat (<15%) content at 6 months after calving.[166]

All high-producing dairy cows have increased amounts of fat (15% to 32% by weight) in the liver before calving 915
and during the first few weeks after parturition[165,166,183] (Fig. 33-7). These fat accumulations in the liver begin 916
before calving as the animal prepares for lactation, and the blood glucose concentration is actually lower before calving.[184] The amount of fat in the liver depends on the amount available and the extent of negative energy balance. Fatter cows tend to lose weight more rapidly and have more fat accumulation in the liver.[165,166] Serum cholesterol values (lipoprotein) are inversely related to loss in condition.[185]

Fig. 33-4 Metabolism of fat in animals with hepatic lipidosis.

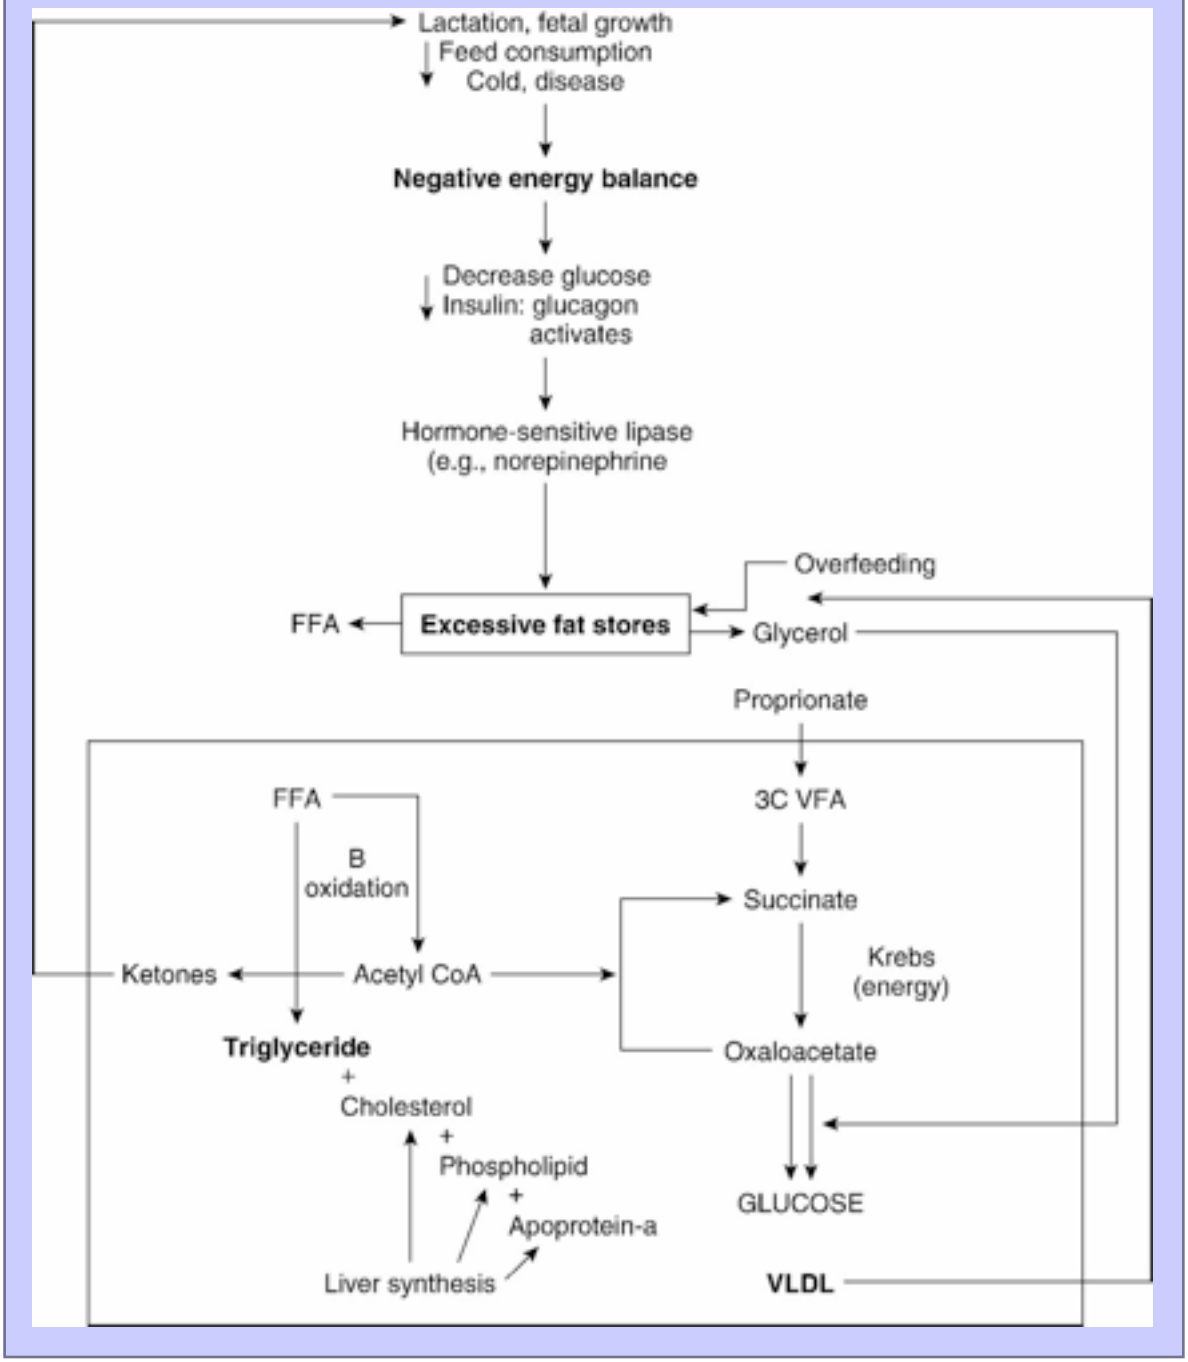


Fig. 33-5 Energy balance (megacalories per day) in normal-condition and obese dairy cows after parturition. From Perkins B: PhD thesis, Ithaca, NY, 1983, Cornell University.

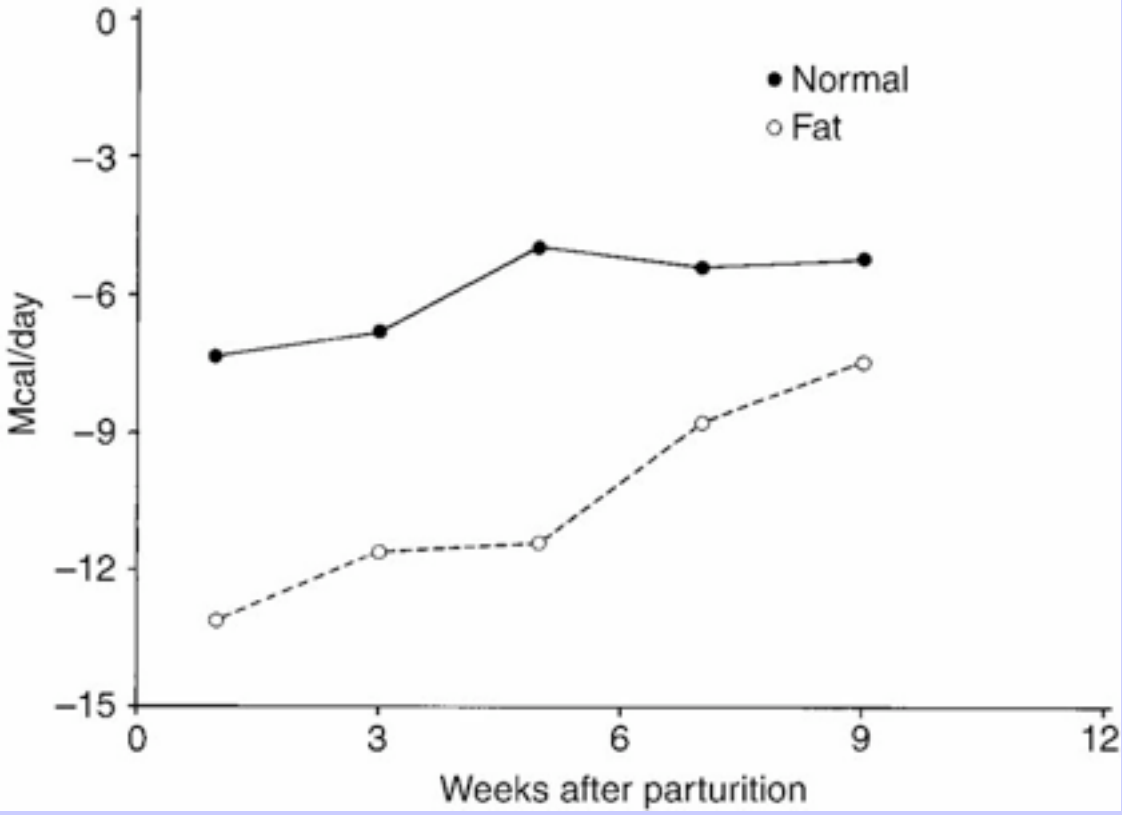

33.25.8 Treatment of Hepatic Lipidosis

The most important principle in treating hepatic lipidosis is the elimination of negative energy balance and the factors or diseases causing it. Continual IV glucose at a rate of approximately 100 to 200 mg/kg/hour may provide continuing energy and induce an insulin/glucagon ratio that will decrease hormone-sensitive lipase mobilization of FFAs and stimulate production of VLDLs. Insulin itself may be given to alter this ratio directly. In cattle, 200 U of protamine zinc (NPH or Lente) insulin is given every 12 hours per 1000 pounds of cow, along with glucose.

916
917

Fig. 33-6 Plasma levels of glucose, insulin, and free fatty acids in dairy cows before and after parturition. From Perkins B: PhD thesis, Ithaca, NY, 1983, Cornell University.

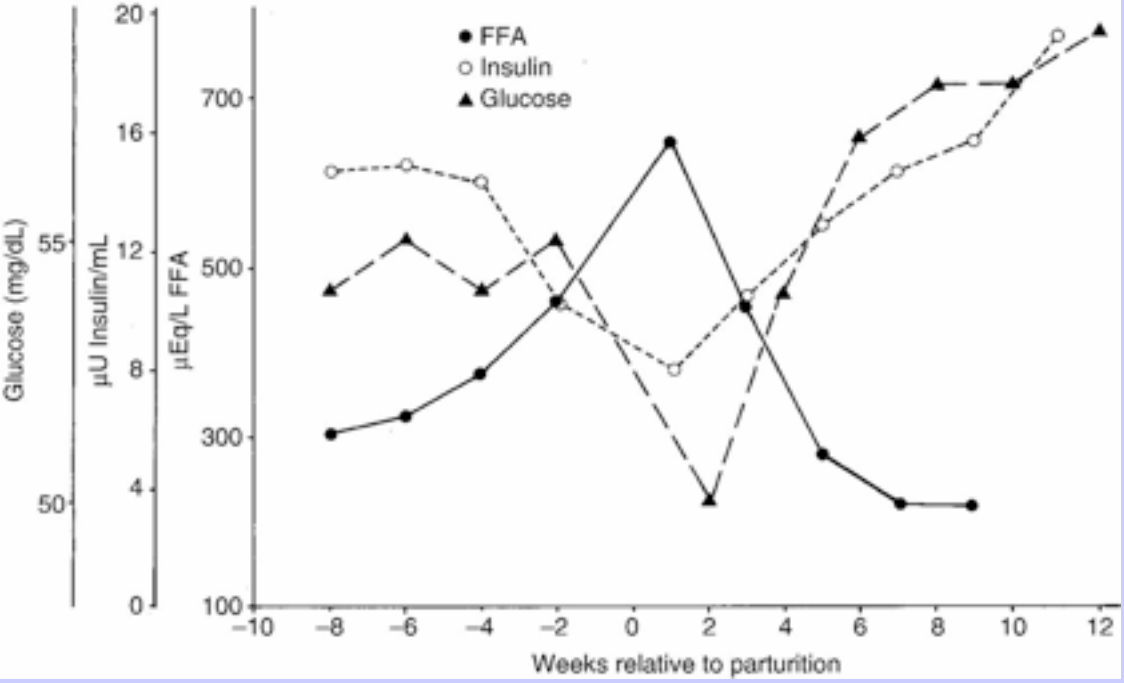

Fig. 33-7 Liver fat as a percentage of total dry weight in normal-condition and obese dairy cows before and after parturition. From Perkins B: PhD thesis, Ithaca, NY, 1983, Cornell University.

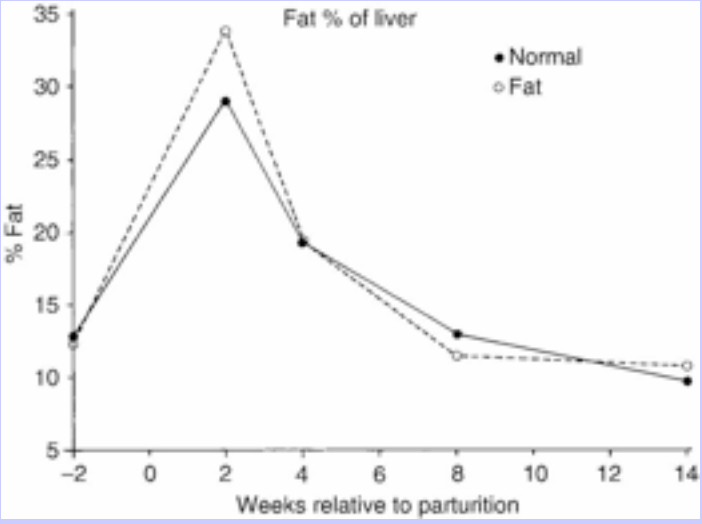

Precursors of lipoproteins such as choline, which is a component of phospholipid, have been advocated to increase the rate at which TGs leave the liver as phospholipids (VLDLs), but no controlled studies have proved their efficacy. Choline is degraded in the rumen,[186] but theoretically, choline chloride (25 g in 250 mL of sterile saline) given subcutaneously could have limited efficacy. Choline should *not* be given intravenously because it acts as a neuromuscular blocking agent. Addition of inositol both before and after birth did not reduce the incidence or severity of hepatic lipidosis.[187] Methionine at 40 to 50 g/day has also been used for the same purpose. Nicotinic acid (niacin) fed at 6 to 12 g/head/day may help reduce lipolysis at the tissue level and thus reduce the amount of fat presented to the liver.[188] Treatment of hepatic lipidosis with nicotinic acid is often associated with a rebound of clinical signs, and its use as a preventive measure is recommended.

Corticosteroids to treat ketosis may be useful but should not be used repeatedly over a long-term period because they may make the animal less resistant to infections.[188] Corticosteroids usually increase appetite, reduce milk production, and induce gluconeogenesis. Both vitamin E and selenium, which function as cellular antioxidants, have been found to be low in many of the cows with fatty liver syndrome;[189] thus, supplementation may be helpful in selected cases.

Digestion in the forestomachs can be enhanced by transfaunating with rumen fluid from a normal cow. This may increase the absorption of volatile fatty acids used for energy and for glucose precursors.

33.26 PREVENTING HEPATIC LIPIDOSIS AND HANDLING NEGATIVE-ENERGY BALANCE AND OVERCONDITIONING

Hepatic lipidosis and associated conditions are most common in dairy cattle. Preventing obesity in cows during late lactation is an important factor in controlling this condition. This process involves a successful breeding program (maintaining a 12- to 13-month calving interval) and closely matching energy in the ration to the level of milk production during late lactation. Once the cow reaches 7 months of pregnancy and the dry period, any dietary restriction below requirements for maintenance and pregnancy are certain to be counterproductive. Table 33-10 lists the recommended nutrient requirements for a 600-kg cow.[190]

917 918

Table 33-10 Daily Nutrient Requirements for 600-kg Cow During Dry Period for Maintenance Plus Last 2 months of Gestation

Body Weight (kg)	NE_1 (Mcal)	TDN (kg)	Total CP (g)	Calcium (g)	Phosphorus (g)
600	12.61	5.5	<31	37	26

NE_1, Net energy of lactation (same as net energy of maintenance) in dairy cows; *TDN*, total digestible nutrients; *CP*, crude protein.

Adequate protein in the dry period is essential.[176,179,180] It has been shown that cows fed higher protein diets during the dry period will perform better in the lactation that follows. Feeding good-quality to excellent-quality roughages (hay, silages) to meet most of these requirements is preferred. Additional grain (starch) 2 to 4 weeks before parturition is important to acclimate the ruminant to anticipated changes in the rations fed after calving. It must be stressed that high-quality dry cow rations be fed *but not overfed*. Dry matter consumption should be limited to approximately 2% of body weight per day while meeting requirements. Other factors in the dry cow

ration also must be considered to prevent periparturient diseases such as milk fever, displaced abomasum, mastitis, metritis, ketosis, ruminal lactic acidosis, and retained placenta.[191] Rations should be adequately supplemented with cobalt, the precursor of vitamin B_{12} that is a cofactor in the rate-limiting step in conversion of propionate (the primary glucose precursor) to succinyl CoA. Nicotinic acid has been included in the dry cow ration at 6 g/head/day and in the early-lactating cow ration at 12 g/head/day to aid in the prevention of ketosis, which is a major risk factor for the development of hepatic lipidosis. The use of monensin in the dry cow ration and the early-lactation ration shows promise to aid in the prevention of ketosis and thus may be of some benefit in preventing hepatic lipidosis.[192,193]

Nutrient requirements increase greatly for beef cattle during the third trimester of pregnancy; these requirements are listed in Chapter 9. As forage quality (digestibility) decreases, the time that feed material stays in the rumen increases (increased rumen turnover time). Therefore, as quality decreases, the maximum dry matter intake (DMI) decreases, which greatly decreases the maximum nutrient (energy) intake. This compounding effect of poor-quality forage on maximum intake is particularly important for preventing hepatic lipidosis and the accompanying protein-calorie malnutrition (PCM) of pregnant beef cattle in the winter. The approximate maximum DMI of forage of poor quality (oat straw, corn stover), medium quality (meadow grass hay), and excellent quality (alfalfa hay [25% crude fiber], corn silage) is 1% to 1.5%, 2%, and 2.5%, respectively. Environmental temperature can increase energy needs for beef cattle on pasture or range; as the temperature falls from 20° C (68° F) to 10° C (50° F), approximately 10% more energy is necessary for maintenance, and at freezing temperatures, 0° C (32° F), 20% additional energy is required. The key to preventing PCM and hepatic lipidosis in pregnant beef cattle is adequate body condition (scores 5 to 7) entering the third trimester and availability of good-quality to excellent-quality forage in adequate amounts.

Preventing pregnancy toxemia and the associated severe hepatic lipidosis in ewes and does requires measures similar to those outlined for PCM in beef cattle. Both overconditioned and thin ewes and does in the third trimester of pregnancy are at increased risk. Because of the common occurrence of twins and triplets, nutrient requirements for pregnant ewes greatly accelerate during this period. Good-quality to excellent-quality forage for feeding sheep is very important. An additional tool for diagnosing underfeeding in ewes is measurement of plasma β-hydroxybutyrate (BHB). This test greatly facilitates assessment of nutritional inadequacy in pregnant ewes.[194] Plasma BHB concentrations of 0.8 mmol/L or higher are diagnostic of the need for increased energy consumption by pregnant ewes.[194] This clinicopathologic tool is of great benefit in diagnosing malnutrition before irreversible pregnancy toxemia develops.

The nutrient requirements of horses and ponies have been covered elsewhere (see Chapter 9). The presence of hyperlipidemia is readily detected and easily solved by increasing caloric intake. Although therapy of hyperlipemic ponies and horses is often unrewarding, the diagnosis is relatively straightforward, and prevention depends on providing adequate feed of good quality.

33.27 CONGENITAL HYPERBILIRUBINEMIA

Erwin G. Pearson

33.28 GILBERT's SYNDROME

Gilbert's syndrome is an unconjugated hyperbilirubinemia in the presence of normal erythrocyte lifespan. It occurs in 7% of humans[195] and has been described in Southdown sheep.[196] Gilbert's syndrome involves a failure of unconjugated bilirubin to cross the liver cell membrane and be conjugated. This is most likely caused by a defect in

carrier proteins or the conjugating enzyme.[197] Hepatic bilirubin clearance is about 30% of normal when tested with a loading dose of radiolabeled bilirubin.[198]

Affected Southdown sheep may have icterus or at least elevated plasma bilirubin levels, both conjugated and unconjugated. Affected sheep also cannot excrete sulfobromophthalein (Bromsulphalein, BSP) into the bile. No histopathologic lesions are present, other than some pigment in the hepatocytes. The condition is inherited as an autosomal dominant trait in humans.[197] The bile acid levels are normal in humans, but one sheep exhibited defects in hepatic bile acid clearance.[199]

33.29 DUBIN-JOHNSON SYNDROME

Dubin-Johnson syndrome is a failure of conjugated bilirubin to enter the bile canaliculi. This has been diagnosed sporadically in humans and in Corriedale sheep.[200] There may be an impairment not only in bilirubin but also in the excretion of other conjugated organic anions. Sheep affected by this syndrome may be jaundiced or have hyperbilirubinemia. Both conjugated and unconjugated bilirubin are increased, and BSP clearance is delayed. Bile acids are reported to be normal in humans, but delayed clearance was reported in three Corriedale sheep.[199] Histologically, the hepatocytes contain a black, melanin-like pigment.[200]

33.30 PERSISTENT HYPERBILIRUBINEMIA IN THOROUGHBREDS

A persistent hyperbilirubinemia has been reported in a Thoroughbred racehorse that had no evidence of liver damage, cholistasis, or hemolysis and was not fasting.[201] The horse was persistently icteric and had serum total bilirubin concentrations of 8.7 to 9.4 mg/dL; 90% or more of the plasma bilirubin was the unconjugated form. Serum bile acid concentration, along with the liver enzymes GGT, AST, and SDH, were within normal limits. The horse acted clinically normal, and the plasma FFA concentration was also within normal limits. The condition was similar to Crigler-Najjar type II syndrome in humans, which involves a deficiency in bilirubin—uridine diphosphate glucuronyltransferase needed to conjugate bilirubin, but this was not verified.

33.31 MISCELLANEOUS LIVER DISEASES

Erwin G. Pearson

33.32 RIFT VALLEY FEVER

Rift Valley fever, also known as *enzootic hepatitis,* is an acute febrile arthropod-borne disease of sheep, goats, cattle, and humans present in most countries of sub-Saharan Africa.[202] With the current threat of bioterrorism, it could appear in other parts of the world. Rift Valley fever is caused by a virus of the genus *Phlebovirus*. More than 20 species of mosquitoes have been implicated as possible vectors for the virus, including some North American mosquitoes that are competent laboratory vectors.[203] The disease causes abortion in pregnant females and a febrile condition with rapid death in lambs, kids, and calves. The mortality rate in young animals approaches 100%, but it is much less (20% to 30%) in older animals.[203] Clinical signs may include fever, anorexia, weakness, salivation, diarrhea, and sometimes abdominal pain, and almost all pregnant animals will abort.[202] The primary gross lesion is hepatomegaly and hemorrhage. Histologically, a focal hepatic necrosis is identified, and eosinophilic intranuclear

inclusion bodies are present.[203] Confirmation of the diagnosis is made in the laboratory by virus isolation or immune tests. If the disease is suspected, state and federal regulatory veterinarians should be contacted.

33.33 TELANGIECTASIA

Hepatic telangiectasia, commonly known as “sawdust livers” in packing houses, is a focal degeneration in liver lobular circulation characterized by red-brown foci 1 to 5 mm in diameter.[204] These lesions account for more than 10% of the bovine liver condemnations but do not result in any clinical signs.[205] Microscopically, hepatocytes are distorted and sinusoids congested.[206] Hypotheses proposed to explain the pathogenesis of the lesions include necrotizing hepatitis, ischemia induced by emboli or other vascular pathologies,[207] dilation of Disse's spaces, reduced density of reticulin framework, vitamin E–selenium deficiency, alteration of the sinusoidal barrier, and immune-mediated disease.[204,205] Some human pathogens have been isolated from these livers as well as normal livers, but livers are condemned on the basis of aesthetics according to current U.S. Department of Agriculture (USDA) regulations.[205]

33.34 ISCHEMIA, HYPOXIA, AND CONGESTION

Ischemia and hypoxia can lead to death of hepatocytes, but less severe insults cause fatty infiltration, because lipoprotein synthesis depends on oxidative metabolism.[204] This damage is more apparent in the centrilobular areas, which are the last to receive blood and oxygen.

Chronic passive congestion causes the grossly visible nutmeg liver. This is caused by the distention of the sinusoids and central veins with blood. The liver may be enlarged in these cases, but other signs related to the liver are not usually present. More significant findings will be detected in the cardiovascular system.

Portocaval shunts are rare in large domestic species but have been described in several foals.[208]

33.35 FETAL LIVER DAMAGE

The liver of the fetus may be damaged by infectious and toxic agents, but the result is usually abortion or birth of a weak neonate with signs related to other systems. The lesions in the liver may be diagnostic of the disease. Equine herpesvirus infection of the fetus causes hepatocyte necrosis, with acidophilic intranuclear inclusion bodies in more than 50% of the hepatocytes. Aborted fetuses of cattle caused by infectious bovine rhinotracheitis may have some focal necrosis of the liver, but not enough to be diagnostic.

33.36 FAILURE OF DRUG METABOLISM AND EXCRETION

A number of drugs are excreted by the liver and may have delayed clearance with hepatic insufficiency. These include antimicrobials such as chloramphenicol, erythromycin, and tetracycline. Chlorthiazide, most steroids, digitalis, morphine, many tranquilizers and anesthetic agents, and lecithin also are removed by the liver, and excretion may be reduced with hepatic insufficiency.[209]

33.37 NEOPLASIA OF THE LIVER

Erwin G. Pearson

Primary neoplasia of the liver is uncommon in large domestic species. Only 0.011% of abattoir animals seen in one study had liver tumors.[210] Metastatic tumors are more common, but the clinical signs of these are more likely to reflect changes at the primary site. Metastasis of lymphosarcoma in cattle is most common, but signs produced by growth in other organs, such as the lymph nodes, abomasum, heart, uterus, and spinal cord, are more predominant. In the horse, lymphosarcomas and carcinomas have metastasized from the digestive tract.[211]

33.37.1 Horses

Although uncommon, a number of different primary hepatic neoplasias have been reported in horses.[212] The nomenclature seems inconsistent throughout the years of reporting, and the signs are usually more consistent with neoplasia in general than with hepatic failure. Weight loss, weakness, anorexia, lethargy, and occasionally colic may be seen in these animals. Serum concentrations of liver-derived enzymes are elevated in many cases. The tumor can often be located by ultrasonography, but the definitive diagnosis of the type of tumor is based on histopathologic examination of biopsy tissue.

Hepatoblastoma has been reported in foals, young horses, and an equine fetus.[213] Young horses present with weight loss or failure to grow, lethargy, anorexia, and possibly icterus. Serum concentrations of several hepatic enzymes are increased. Ultrasonography reveals hepatomegaly and a heterogenous appearance of the hepatic parenchyma. Erythrocytosis is seen in some cases because of a paraneoplastic syndrome and increased production of erythropoietin.

Hepatocellular carcinoma is seen in both old and young horses. These horses lose weight and are listless. Serum concentrations of LDH, GGT, and AST are often elevated. Erythrocytosis with a normal concentration of serum protein is seen in most cases as a result of paraneoplastic syndrome with elevated erythropoietin.[212,214]

Cholangiocarcinoma or cholangiocellular carcinoma arises from the intrahepatic bile duct epithelium and appears to be a disease of older horses.[215] Lethargy, fever, abdominal pain, anorexia, and ventral edema have been reported with this tumor. Some of these animals have anemia rather than the erythrocytosis reported with hepatocellular tumors. GGT and ALP concentrations may be elevated, but SDH (which comes from hepatocytes) is usually within normal range.

33.37.2 Cattle

In addition to the lymphosarcomas, primary hepatocellular carcinomas have been described in cattle.[216] Liver-derived enzymes may be elevated, and polycythemia (erythrocytosis) is a common laboratory finding in these cases.[217]

33.38 HEMOCHROMATOSIS

John Maas

Erwin G. Pearson

Hemochromatosis is a disorder caused by deposition of hemosiderin in the parenchymal cells, resulting in tissue damage and dysfunction of the liver and other tissue. It is most frequently seen in humans and mynah birds, but

hemochromatosis has been described as a new disease of Salers cattle[218] and has been reported in three horses.[219] In people the types include idiopathic hemochromatosis, an autosomal recessive familial condition associated with increased iron stores, cirrhosis, and saturation of the iron transport capacity.[220] Both horses and cattle show increased iron deposits in the liver; histopathology of liver biopsy specimens reveals brown pigment that stains for iron in the hepatocytes as well as Kupffer's cells. An increased concentration of iron can be measured in the liver, and there is fibrosis and elevated liver-derived enzymes.

In Salers cattle the condition appears to be a homozygous recessive condition more like the human familial type. There is an inappropriate absorption of iron (Fe) by the GI tract, with subsequent hepatic storage (Fe overload) and eventual loss of hepatic function. It has been reproduced by experimental breeding in Salers cattle.[221] The primary clinical signs in cattle are decreased weight gains, poor body condition, dull hair coat, loss of incisor teeth, and sometimes diarrhea. Serum concentrations of liver enzymes are elevated, and there is marked hepatic fibrosis, in addition to the hemosiderin deposits in the liver. Total serum Fe, total iron-binding capacity (TIBC), and saturation of transferrin (>60%) are increased, similar to the familial disease in humans. Liver iron concentration will be greater than 5000 µg/g (ppm) on a wet basis (normal herdmates of affected cattle, 84 to 100 ppm).[222]

Horses with hemochromatosis present with evidence of liver disease. Serum concentrations of the liver enzymes ALP, GGT, and AST are elevated; and serum total bile acids are greater than 40 µM/L. In the cases reported, total serum iron was not elevated, and unlike the idiopathic human condition or the cattle cases, there was no saturation of the iron-binding capacity. Total liver iron has been as high as 6700 ppm (normal, 100 to 300 ppm).[219]

Hemochromatosis should be suspected in animals with emaciation or elevated liver enzymes and in Salers cattle with greater than 60% saturation of transferrin. It is confirmed by histopathologic examination of the liver, with excessive iron accumulation in hepatocytes. Clinicians should differentiate hemochromatosis from *hemosiderosis,* in which iron accumulates in the reticuloendothelial system and not hepatocytes, and which can be caused by hemolysis and other conditions.

In humans, hemochromatosis is treated by reducing the iron stores through phlebotomies and blood removal. The one horse on which this was tried had advanced disease with severe cirrhosis, and it succumbed a few days after the blood removal. Removal of 160 L of blood over 12 months failed to reduce liver iron concentration in one heifer[218] but produced some improvement in other calves.[221] Deferoxamine is given to some human patients to induce a negative iron balance and reduce the rate at which iron accumulates.

33.39 GALLBLADDER AND BILIARY TRACT DISEASE

Terry C. Gerros

Biliary tract disease in large animal medicine is rare and results from both intrahepatic and extrahepatic causes. Intrahepatic causes of cholestasis include cholangitis, cholecystitis, choledocholithiasis, and presence of a foreign body. Extrahepatic causes include abscess formation, inflammatory disease near the common bile duct, and neoplasia.

33.40 CHOLEDOCHOLITHIASIS, CHOLELITHIASIS, HEPATOLITHIASIS

By definition, *cholelithiasis* describes the presence of biliary calculi in either the bile ducts or the gallbladder, whereas *choledocholithiasis* describes stones found in the common bile duct. *Hepatolithiasis* indicates the presence of calculi in the intrahepatic bile ducts above the right and left hepatic ducts and is a variation of cholelithiasis.

These conditions have been described in horses, cattle, sheep, and pigs; however, they do not seem to be recognized as a clinical problem in sheep, and rarely in cattle.[223–244] Choledocholithiasis is the most common cause of biliary obstruction in large animals and occurs more frequently in horses.[223–236]

Biliary stone formation begins with the precipitation or aggregation of normally soluble components of bile. Other mechanisms involved in the pathogenesis include ascariasis, ascending biliary infection or inflammation, biliary stasis, changes in bile composition, and presence of a foreign body.[228,243] Several pathogenic bacteria (*Salmonella* species, *Escherichia coli, Aeromonas* species, *Citrobacter* species, group D *Streptococcus* species, *Clostridium perfringens*) have been cultured from the bile ducts of horses and cows with cholelithiasis.[224,234,238,245] Whether these bacteria were the cause or the result of the stone formation remains unclear. In most reports the chemical analysis has shown that choleliths have a mixed composition, containing bilirubin, bile pigments, cholesterol esters, esters of cholic and carboxylic acid, calcium phosphate, and sodium taurodeoxycholate.[225,228,234,236,238] In one study, 80% of the choleliths contained less than 10% cholesterol.[238]

33.40.1 Clinical Signs, Diagnostic Test, and Differential Diagnosis

Cholelithiasis should be suspected in horses when a triad of clinical signs exists: recurrent abdominal pain, pyrexia, and icterus. Hyperammonemic hepatic encephalopathy, photosensitization, and weight loss are other, less common features of cholelithiasis.[226–229,233,234,243,245] A subclinical presentation, caused by partial obstruction of the biliary tree, may be recognized only on postmortem examination.[239] A large cholelith was the cause of duodenal obstruction in a horse presented for colic.[240]

Elevations in the serum activity of ALP, AST, GGT, SDH, and total bilirubin are associated with cholelithiasis.[226–229,234,238,243,245] The rise in total bilirubin is caused by an elevation in both direct and indirect bilirubin. In the horse, cholestasis should be suspected if more than 25% to 30% of the total bilirubin is the direct type.[223] Serum bile acid concentrations also increase when bile flow is obstructed.[246] Other laboratory abnormalities that may be seen include hyperammonemia, increased urine bilirubin, and prolonged partial thromboplastin and thrombin times.[225,229,233,234,238] The most common alterations in the leukogram include a neutrophilic leukocytosis. Elevations in globulin and fibrinogen may also occur.[225,226,228,233]

Ultrasound examination of the liver is a safe, noninvasive tool for diagnosing cholelithiasis. Hepatomegaly and bile duct dilation are seen in horses with biliary calculi. The echogenicity of the hepatic parenchyma is increased compared with that of normal horses and may approach that of the spleen; the bile ducts are thick and distended. The parallel channel sign (dilation of interhepatic biliary radicals adjacent to portal vein) may also be seen. Several choleliths generally are seen, but a single stone may be present. Choleliths may be hyperechoic, casting acoustic shadows, or they may be sonolucent. Choleliths are most likely to be visualized in the cranioventral part of the right hepatic lobe, especially in the sixth to eighth intercostal spaces. Cholelithiasis can accurately be diagnosed by ultrasound in at least 75% of horses if an adequate scanning image of the liver is obtained and bile duct dilation and choleliths are visualized.[236]

The differential diagnosis for a horse with the clinical signs associated with cholelithiasis include other causes of liver disease and mild, recurrent abdominal discomfort, including verminous arteritis, mesenteric abscesses, enterolithiasis, abdominal neoplasia, and urolithiasis.[226,227]

33.40.2 Necropsy Findings

Hepatomegaly is usually noted at necropsy, although a shrunken liver may be observed. The liver is firmer than normal, has a consistent texture, and varies in color from red to green-brown. The hepatic ducts and common bile duct are generally dilated and may contain the calculi. Histologically, periportal fibrosis is a common finding. Bile duct stasis and hyperplasia are usually noted; suppurative cholangitis is less common.[225,238,243,245]

33.40.3 Treatment

Treatment of cholelithiasis includes relief of biliary flow obstruction and management of hepatitis and associated complications. Choledocholithotomy and choledocholithotripsy, described in horses, have had limited success.[233–235] Because the potential for bacteremia with surgical manipulation for cholelithiasis is high, treatment with potentiated sulfa drugs, ampicillin, tetracycline, or chloramphenicol before surgical intervention is warranted. In humans, chenodeoxycholate or ursodeoxycholate is used to dissolve cholesterol gallstones;[247] their use has not been reported in animals. Dietary management for cholelithiasis has yet to be determined.

The prognosis remains guarded for horses with cholelithiasis or choledocholithiasis.

33.41 DISEASES OF THE GALLBLADDER

33.41.1 CHOLANGITIS

Clinical disease of the bovine gallbladder is rare. Obstructive gallbladder disease has been associated with abdominal fat necrosis, choleliths, fascioliasis, foreign bodies, hepatic abscesses, neoplasia, and suppurative cholecystitis.[248,249] Adenomas and adenocarcinomas (most common tumors found in gallbladder), papillomas, and lymphosarcoma (rare) can cause obstruction.[248,250] Rupture of the gallbladder was found on necropsy of a cow in which icterus, anorexia, decreased milk production, and diarrhea had been present.[251]

Cholangitis is considered the most common cause of bile duct obstruction in large animals and has also been observed in horses with chronic active liver disease. Clinical signs associated with cholangitis in the horse may include anorexia, subtle behavioral changes, chronic weight loss, colic, and icterus. Alterations in hepatic enzyme activity may indicate either hepatocellular damage or cholestasis, or both. Histopathologic examination and bacterial culture are indicated to further identify the causative agent. In cases of suspected bacterial etiology, long-term antibiotic therapy is indicated.[252] The antibiotic choice should be based on bacterial sensitivity; however, in cases in which no bacterial organism is identified, an antibiotic that is secreted or cleared in the bile is warranted.

Several foreign bodies have been recovered from the biliary tract, including grain, nails, sticks, stones, and sand. Retrograde motion of the intestine may have allowed these foreign bodies to enter the duodenal papilla and become lodged.

33.41.2 CHOLANGIOHEPATITIS

Cholangiohepatitis has been reported both as a primary disease and as occurring secondary to cholelithiasis, duodenal inflammation, intestinal obstruction, neoplasia, parasitism, and certain toxins.[253] Sporidesmin, a fungal toxin from *Pithomyces chartarum,* causes cholangiohepatitis in cattle and sheep.[254] Horses with cholangiohepatitis, either primary or secondary, may show anorexia, icterus, pyrexia, and intermittent signs of colic.[243,253] Biochemical analysis revealing elevated cholestatic and hepatocellular enzyme activity and conjugated hyperbilirubinemia, combined with inflammatory leukogram, supports a diagnosis of cholangiohepatitis. Hyperammonemic hepatic encephalopathy may also be a feature. Cholangiohepatitis can be successfully treated in the horse, which primarily depends on long-term antimicrobial therapy and supportive treatment with IV fluids.[255] Treatment failure is associated with hepatic biopsy results and inadequate treatment duration. Severe periportal and bridging fibrosis with or without hyperammonemic hepatic encephalopathy carries a poor prognosis. Clinical recovery may be seen before normalization of biochemical indices of hepatobiliary function. GGT levels may increase during the early stages of treatment, before they decrease. It is recommended that treatment be continued until GGT levels return to normal.[255]

33.42 THERAPY OF LIVER FAILURE

Thomas J. Divers

Hepatic failure usually is treated medically and supportively, although surgery may be indicated in a few cases. Therapy is best indicated in cases of acute liver failure without chronic fibrosis, such as with serum hepatitis, suppurative cholangitis, and toxic hepatopathies other than with pyrrolizidine alkaloids, because these animals have the best long-term prognosis for regeneration. Prognosis is generally poor if severe hepatoencephalopathy or hemolysis or severe acidosis or diarrhea is present. The initial therapy for hepatic failure should be directed toward any abnormal behavior (hepatoencephalopathy) the patient may be exhibiting.[256]

Hepatoencephalopathy (HE) is a metabolically induced, potentially reversible, functional disorder of the brain. The pathophysiologic mechanisms of HE are undoubtedly complex but mostly result from abnormal protein metabolism.[257,258] Cerebral edema is characteristic of HE in humans, but it is rarely observed on microscopic examination of the brain in dying horses with HE. Complex interactions of both excitatory and inhibitory neurotransmitters determine if the patient is depressed or manic.[259]

If the animal is extremely agitated or convulsing, sedation should be accomplished before attempting further therapy. Detomidine will provide adequate sedation in most cases and is the drug of choice for horses with manic behavior caused by the HE. Most sedatives and tranquilizers are metabolized by the liver, so their use should be kept to a minimum, and doses of detomidine that cause marked lowering of the head or abnormally low respiration should be avoided. Diazepam should be avoided in animals with HE because it may enhance the effect of GABA on inhibitory neurons and worsen HE signs.[260] The use of the benzodiazepine receptor antagonist flumazenil has been reported to lessen HE signs temporarily in humans.[261] The overall success of flumazenil in treating HE in humans and dogs has been low, and it has rarely been used in the horse. Sarmazenil, which has a different mechanism of action, appears to be more promising for reversing signs of HE in some humans and has been used for treating moxidectin intoxication in a foal.[262,263]

After chemical restraint of the affected animal, therapy can be directed at the physiologic events that may be causing HE. If the blood glucose concentration is low, 0.2 to 0.4 mL/kg of a 10% glucose solution should be initially administered intravenously. This may result in a dramatic alleviation of the clinical signs of HE in a few cases (e.g., Theiler's disease, hepatic neoplasia, Tyzzer's diseases). Therapeutic measures directed toward decreasing the blood ammonia concentration are also indicated. These include oral administration of neomycin at 10 to 30 mg/kg two or four times daily for 1 or 2 days, either alone or in combination with oral lactulose (90 to 120 mL per adult horse three or four times daily), or oral acetic acid at 0.5 mL/kg twice daily.[264,265] A carbohydrate and prebiotic, lactulose is poorly absorbed from the small intestine and in the large intestine may decrease colonic pH and enteric ammonia concentration. Vinegar (acetic acid) should do the same. Metronidazole (10 to 15 mg/kg twice daily) may also be used to decrease ammonia-producing bacteria but is not preferred because it is metabolized by the liver, and signs of toxicity may mimic HE.

Nasogastric intubation should be performed with care because excessive trauma to the nasal cavity, esophagus, or stomach may result in severe and prolonged hemorrhage, swallowing of blood, and worsening of HE. Therefore, I prefer to administer oral drugs by dose syringe mixed with molasses and Karo syrup. Neomycin administration should not be prolonged because this may have a toxic effect on the intestinal mucosa[266] and cause severe diarrhea in some horses. Following neomycin therapy, probiotics can be given, some of which may result in decreased intestinal ammonia production.[267] Some clinicians prefer not to treat with oral drugs that affect intestinal flora, but rather to rely mainly on a low-protein diet and a laxative.

Acidosis may be severe in many horses with hepatic failure, but attempts at correction must be made slowly.[264] Too rapid an increase in pH may exacerbate the HE. I recommend bicarbonate therapy only when the venous pH is less than 7.1 and IV therapy with an alkalizing, balanced electrolyte fluid has failed to improve the acidosis. The prognosis is poor in horses that maintain persistent acidosis. It is of utmost importance that dehydration be corrected with a balanced electrolyte solution (preferably without lactate), dextrose (20 to 50 g/L), and supplemental potassium (20 to 40 mEq/L). Additional potassium should also be given orally (5 to 20 g twice daily). Maintaining potassium intake is important because low potassium increases production and absorption of ammonia from the kidney.[268]

Urine dipstick and plasma glucometer measurements should be used to monitor glucose concentration. Although most adult horses with hepatic failure have normal blood glucose concentration, it is important to supplement the fluids with glucose unless the horse is hyperglycemic. Glucose decreases ammonia concentration, reduces the reliance on catabolic gluconeogenesis, decreases protein catabolism, and spares hepatic energy consumed in hepatic gluconeogenesis. Glucose must not be given as the sole source of fluid. It is also important that glucose be continually maintained within the normal range (90 to 120 mg/dL). Polycythemia may be relatively unresponsive in some cases of hepatic failure and should not be used as the primary guide for judging adequate fluid therapy. Fresh or fresh-frozen plasma can be used, to increase colloidal oncotic pressure, clotting-factor transport proteins, and antiproteases. Stored whole blood should not be used because ammonia levels may be high. Hetastarch should also not be used in hepatic failure.

Antioxidant, antiinflammatory, and antiedema therapy may be useful in some cases of acute hepatic disease and failure. Dimethyl sulfoxide (DMSO), acetylcysteine, vitamin E, and mannitol are antioxidant and antiedema drugs that may be useful.[269] *S*-adenosylmethionine (SAMe) appears to have protective effects against oxidative hepatic injury and is the preferred antioxidant for therapy in equine hepatic disease.[270] Antiinflammatory therapy should include flunixin meglumine and pentoxifylline (7.5 mg/kg PO every 12 hours). Horses with acute hepatic failure

that cannot be controlled by this therapy would require extracorporeal liver support systems. Although these have not been used in the horse, dialysis, charcoal adsorption, or plasma exchange methods are available.[271]

Treatment of ponies with hyperlipemia is covered in the section on hepatic lipidosis. If the hyperlipemia is thought to be associated with a pituitary adenoma, the treatment with pergolide (1 to 5 mg/day) is warranted and may be successful. Hyperlipidemia may also occur in horses in late pregnancy associated with diarrhea and azotemia.[272] If the pony or horse is in late pregnancy, it may be advisable to abort the mare.[273] Fatty liver in ruminants is discussed on p. 912. Hepatic failure in cattle associated with septic metritis or mastitis and in those with biliary obstruction from hepatic abscesses can often be successfully treated by forced feeding (e.g., alfalfa gruel, electrolytes) and systemic antibiotics.[274] Treatment of hepatic fascioliasis is discussed on pp. 909 and 910.

Animals with hepatic disease that maintain a fair appetite often are best treated by dietary management. Dietary management is important in the recovery of animals with acute hepatitis or hepatopathy and in prolonging the life of those with chronic hepatic disease. Energy and protein requirements (especially branched-chain amino acids) should be met.[275] An example of a reasonable diet is one part beet pulp with one-quarter to one-half part cracked corn mixed with molasses four to six times daily. Milo or sorghum may also be used as a grain mix. Small meals given frequently are ideal because of difficulties with gluconeogenesis and insulin regulation. Sorghum, oat hay, or grass hay may be substituted for beet pulp. If the affected horse will not eat, forced feeding should be considered, but nosebleeds should be avoided. An oral paste with a high branched-chain/aromatic amino acid ratio can be formulated or purchased for forced feeding.[276] Vitamin B_1, folic acid, vitamin K_1, or fresh plasma transfusion might be indicated with chronic biliary obstruction. Grazing of mixed grasses is permitted and should be encouraged, as long as affected horses can be protected from sunlight. Spring-cut hay or grass should be limited because these can be very high in protein. Alfalfa is also generally high in protein and is best avoided with hepatic dysfunction, except in cows that seem to be more tolerant of high-protein feeds. It is important that a horse with hepatic failure eat something, even if it is not one of the more desirable feeds previously mentioned.

Bactericidal antibiotic therapy is indicated for horses with bacterial cholangitis and in cattle with liver abscesses. A diagnosis of suppurative bacterial cholangitis usually is made before the organism or its antibiogram is known. Therefore, broad-spectrum aerobic drug therapy, such as a combination of ampicillin and gentamicin, trimethoprim-sulfa, ceftiofur, or enrofloxacin, is preferred for the initial therapy. Anaerobic organisms may also be involved, and metronidazole can be added to any of these drug therapies. Antimicrobial therapy can be adjusted if the offending organism can be identified from a liver biopsy. Gram-negative enteric organisms are the most common causative organisms, and in my experience, only 50% or less are sensitive to trimethoprim-sulfa. This is unfortunate, since prolonged (2 weeks to 3 months) antibacterial therapy is usually required for suppurative cholangitis.[277] Ultrasound examination is important in treating equine suppurative cholangitis because some cases are associated with biliary stones, which makes the treatment more difficult and worsens the prognosis. If there are small obstructing stones or sludge, DMSO (0.5 to 1.0 g/kg IV for 3 to 5 days) may help dissolve the calcium bilirubinate stones or debris.[278] IV crystalloids may also thin secretions and promote bile flow. Ursodeoxycholic acid, a commercially prepared bile acid, is used for a variety of chronic biliary disorders in humans and small animals and will induce choleresis. This drug's benefit in horses has not been proved, and safety is a concern because rabbits, which have a GI system similar to the horse, metabolize this bile acid into noxious bile acids.[279] If a large, obstructing stone is present, surgery is indicated. Although the most distal bile duct opening into the duodenum cannot be visualized by ultrasound examination, it can be seen during gastroduodenal endoscopy.

Cattle with singular or multiple liver abscesses often respond to penicillin therapy, but long-term therapy is required, and there is a significant rate of recurrence of clinical signs after therapy is withdrawn. Abscesses of small

to medium size and echolucent have the best prognosis. Abscesses with echodense appearance are difficult to treat. Single, large abscesses are best treated by surgical drainage, especially those interfering with vagal nerve function. High levels of IV penicillin and an aminoglycoside should be administered to foals with suspected Tyzzer's disease. Penicillin in high dosages and/or metronidazole should also be used for treating suspected anaerobic abscesses of the liver. Foals with salmonellosis should be given antimicrobial therapy based on culture and sensitivity results from previously affected foals on the same farm and from results of blood and fecal cultures of the affected foal.

Surgery may be indicated as part of the therapy for liver failure in foals with duodenal stricture or in horses with colonic displacements (usually 180 degrees volvulus) that result in biliary obstruction.[280] Foals and calves with portosystemic shunts require surgical repair if desirable growth and performance are expected.[281] Surgery for cholelithiasis is indicated if there is an obstructing stone and unless diffuse fibrosis is already present. Cattle with a single, large hepatic abscess or calves with an umbilical vein hepatic abscess are best treated by surgical drainage.

Horses thought to have chronic active hepatitis with bridging necrosis that is not believed to be associated with a bacterial infection may be given corticosteroids, pentoxifylline, and/or colchicine (0.03 mg/kg orally every 24 hours), but the therapeutic benefits of these drugs appears to be variable. If steroids are to be used, 200 mg of prednisolone orally per day for the adult horse is recommended.

33.43 PANCREATIC DISEASE

Terry C. Gerros

Pancreatic disease is rare in both cattle and horses. In the horse, acute and chronic disease has been reported, whereas only chronic disease has been reported in cattle.

Recognized causes of pancreatitis include migrating parasites; bacterial and viral infections; immune-mediated damage; biliary or pancreatic duct inflammatory disease; deficiencies of vitamin A or E, selenium, and methionine; and vitamin D toxicity.[282–285] Drugs known to induce pancreatitis in humans that are used frequently in horses include furosemide, tetracycline, estrogen, and certain corticosteroids and sulfonamides.[282,284] One case report in a pony suggests an association with Cushing's syndrome.[286] The cause of acute pancreatitis in the horse is unknown; however, it has been associated with grain overload and severe abdominal pain.[287] The final common pathway may result from autodigestion by activated enzymes, but the exact mechanism remains speculative. Pancreatitis was also diagnosed postmortem secondary to severe gastroduodenal ulceration in a foal.[288]

The clinical signs associated with acute pancreatitis are not specific and mimic those associated with an acute GI crisis. The characteristic clinical features are moderate to severe abdominal pain, gastric reflux, hypovolemic shock, and cardiovascular compromise.[282,285,289,290] Gastric distention accounts for the pain and gastric reflux associated with acute pancreatitis. Hypovolemic shock, occurring secondary to fluid losses into the peritoneal cavity and bowel lumen, results from the release of vasoactive substances from the pancreas. Tachycardia, tachypnea, prolonged capillary refill, and congested mucous membranes result from hypovolemia and cardiovascular compromise.

Laboratory confirmation of pancreatic disease is difficult and not routinely attempted. The diagnosis is usually confirmed on histologic evaluation of the pancreas after necropsy. Laboratory tests that may be of value in the diagnosis of pancreatitis in the horse include measuring serum amylase and lipase activity, peritoneal fluid (PF) amylase concentrations, fractional excretion of amylase, and plasma trypsin levels.[285] Serum amylase values from normal horses range from 14 to 35 IU/L (mean, 21 ± 6), whereas PF values range from 0 to 14 IU/L (mean, 5 ± 4).

[291] Elevations of pancreatic enzyme activity are difficult to interpret, because the enzymes may be elevated in horses with proximal enteritis, colic, primary renal failure, and damage to intestinal mucosal cells, as well as in pancreatitis.[285,291,292] Amylase also originates from the salivary glands, and lipase can be released from the liver. Clinical cases documented at necropsy had serum amylase activity greater than 700 IU/L; this magnitude of elevation may be helpful in differentiating acute pancreatitis from other causes. In acute pancreatitis, PF amylase levels are higher than serum levels.[292] Plasma trypsin levels increase in horses with suspected pancreatic damage and may be a better indicator of pancreatic disease.[293] Trypsin is specific to the pancreas and activates its own zymogen and those of all the other pancreatic enzymes. In one study, in horses with acute abdominal disease in which pancreatic damage was suspected, trypsin activity was significantly higher than in healthy horses (196 ± 128.2 ng/mL vs. 28.5 ± 19.2 ng/mL).[293] Pancreatitis has not been imaged successfully in the horse with ultrasonography.[294] A technique for ultrasound examination of the right lobe of the pancreas in healthy cattle has been described.[295]

Medical management of acute pancreatitis is symptomatic. Prevention of gastric rupture by continuous gastric decompression and control of abdominal pain are crucial in the treatment of pancreatitis.[284] Large volumes of balanced polyionic electrolyte solutions are necessary to maintain the circulating volume and prevent shock. Because hypocalcemia may be a problem, serum calcium concentration should be monitored. Broad-spectrum antibiotics are warranted because of the potential for secondary bacterial infection. NSAIDs and analgesics are used to control inflammation and pain.

Chronic interstitial pancreatitis (CIP) in horses and cattle seldom has clinical significance. In horses, *Strongylus equinus* and *Stronglyus edentatus* are most often identified as the etiologic agent of CIP; however, *Parascaris equorum* has been identified in one case report.[284,296,297] In cattle, CIP has been primarily associated with the trematodes *Eurytrema pancreaticum* and *E. coelomacticum*; these parasites have not been isolated in the United States.[292]

Reports of pancreatic disease in adult cattle have been limited to endocrine dysfunction.[298–300] The most frequently reported disorder is type I diabetes mellitus; however, the etiology in most cases is not determined.[298–300] Histopathologic examination generally reveals an absence of β-cells in the islet tissue. Foot-and-mouth disease virus has been associated with diabetes mellitus in cattle following convalescence.[292] Hypoplasia of the acinar pancreatic tissue has been described in calves.[292] Clinical signs include steatorrhea and diarrhea. Adenocarcinoma of the exocrine pancreas is reported in rare equine cases and should be considered in horses exhibiting the clinical signs of pyrexia, depression, weight loss, and icterus.[283,301,302]

Pancreatic calculi found in older cattle (>5 years) during necropsy are considered incidental findings.[292,303] The calculi are composed primarily of calcium carbonate and calcium phosphate. Their presence may be associated with grazing on silica-rich soil, vitamin A deficiency, or chronic inflammation of the pancreatic ducts.[292]

34.1 EQUINE RENAL SYSTEM

34.1.1 ACUTE RENAL FAILURE

THOMAS J. DIVERS

Acute renal failure (ARF) in the horse is usually a consequence of exposure to nephrotoxins or vasomotor nephropathy (e.g., hypoperfusion or ischemia). The most common pathologic lesion with ARF is acute tubular necrosis (ATN).

34.2 TOXIC NEPHROPATHIES

34.2.1 Aminoglycosides

Administration of aminoglycoside antibiotics is one of the most common causes, if not the most common cause, of ATN in the horse. Neomycin is the most nephrotoxic of the aminoglycosides, followed by gentamicin, kanamycin, and amikacin (all three of similar toxicity), with streptomycin being the least nephrotoxic. The aminoglycoside antibiotics exert their toxic effect by accumulating within proximal tubular epithelial cells. Their entrance into the tubular epithelial cell is thought to be via urine, after filtration through the glomerulus.[1] Once toxic amounts are sequestered within the cell, cellular metabolism is disrupted, and tubular cell swelling, death, and sloughing into the tubular lumen occur. Release of lysosomal enzymes and intracellular accumulation of calcium are likely involved in cell death.

Most cases of aminoglycoside nephrotoxicity are not the result of overdosing of the drug or administration of the drug to an azotemic patient.[2] The healthy kidney can usually tolerate a single major overdose (i.e., 10 times the normal amount) without detrimental effects. Toxicity is almost always the cumulative effect of repeated administration of aminoglycosides. Nephrotoxicity typically develops after several days of aminoglycoside administration to horses with diarrhea or septicemia that are not adequately hydrated,[3] or because of other factors that may exacerbate a decrease in renal perfusion (e.g., concurrent treatment with nonsteroidal antiinflammatory drugs [NSAIDs]). Prolonged administration (>10 days) of aminoglycoside antibiotics without monitoring of aminoglycoside trough concentrations or serum creatinine concentration is a common history with aminoglycoside nephrotoxicity in the horse. Gentamicin or amikacin may be safely administered for longer than 10 days if the patient is adequately hydrated and appropriate trough concentrations and creatinine concentration are maintained. With regard to the latter, experimental induction of gentamicin nephrotoxicity in ponies was reflected by a rather small increase (0.3 mg/dL) in creatinine.[4]

Although it has not been proved that the neonatal equine kidney is more susceptible to aminoglycoside toxicity than the adult kidney, sick foals appear to be at greater risk for aminoglycoside nephrotoxicity.[5] This apparently greater risk may simply reflect an increased incidence of septicemia in sick neonates and longer courses of treatment with aminoglycosides. Nevertheless, special attention (close monitoring of trough concentrations and creatinine) should be given to premature or young foals that are being treated with aminoglycoside antibiotics.[6]

When aminoglycosides are administered to high-risk patients (those with concurrent dehydration or neonates), volume deficits must be replaced, and serum trough concentrations or creatinine should be monitored frequently.[7] Aminoglycoside nephrotoxicity rarely develops in horses receiving appropriate fluid therapy. Increased urinary sodium excretion and fluid diuresis appear to have a protective effect on the kidney. In contrast, hypokalemia (or total body potassium depletion) and low calcium intake may predispose horses to aminoglycoside nephrotoxicity by decreasing urine output.[8] Supplementation with oral electrolytes (e.g., 1 to 2 oz of NaCl and KCl daily) may be of benefit to horses being treated with aminoglycoside antibiotics by increasing water intake and urine output and by replacing potassium deficits in anorectic horses. In contrast, furosemide should not be administered prophylactically in an attempt to prevent aminoglycoside nephrotoxicity.[9] The recent shift to once-daily aminoglycoside dosing, compared with previous dosing of aminoglycosides two or three times daily, has become a standard practice that likely reduces the potential for nephrotoxicity (by ensuring a longer period of the day with appropriate serum trough concentrations) but still provides a similar therapeutic response.[10–13]

In patients with prerenal azotemia that receive aminoglycoside antibiotics, it is important to monitor creatinine closely and to consider prolonging the interval between drug administration until volume deficits are corrected. However, because nephrotoxicity is a cumulative effect of repeated dosing, delay of administration of the initial dose of an aminoglycoside pending rehydration of a critical patient (e.g., septic neonate, extremely dehydrated horse) is unwarranted.

Aminoglycoside nephrotoxicity should be considered in horses that become inexplicably depressed and inappetent while being treated with aminoglycosides or within a few days after aminoglycoside therapy is discontinued. Renal failure can develop even after the drug is withdrawn; thus, monitoring renal function 2 to 4 days after discontinuing aminoglycoside therapy may be advised in high-risk patients. Polyuria may be observed before the onset of depression and anorexia or, if the patient becomes oliguric, mild stranguria and repeated posturing to urinate may be observed. A tentative diagnosis of nephrotoxicity is based on history of aminoglycoside use and supportive laboratory data. Abnormal laboratory findings associated with tubular damage that may be detected before onset of azotemia include enzymuria and cylindruria.[4,14] Although these parameters can be monitored for early detection of tubular injury, their finding does not necessarily indicate if or when aminoglycosides should be discontinued or to what degree the interval of administration should be prolonged.[15]

925

926

When ARF from aminoglycoside use develops, it is usually manifested as nonoliguric to polyuric renal failure, and outcome is generally favorable as long as the duration of ARF is not prolonged and other underlying disease processes can be corrected. Peritoneal or pleural dialysis, plasmapheresis, or hemodialysis might be considered as methods to lower serum concentrations of nephrotoxic agents and uremic toxins; however, the amounts removed by a single use of some of these therapies are small and generally not worthy of pursuit in horses with nephrotoxic renal failure.[16]

34.2.2 Pigment Nephropathy

Acute tubular necrosis and development of ARF consequent to rhabdomyolysis is uncommon unless the tying-up episode is severe or the associated dehydration is prolonged.[17] Observation of grossly discolored urine is not a prerequisite for the development of renal failure. Hemolysis appears to be a less common cause of pigment nephropathy than myopathy, although ARF can occur sporadically. Horses with severe hemolysis or those with hemolysis accompanied by disseminated intravascular coagulation (DIC) are at greater risk of developing pigment nephropathy.[18] Although 40% of the 32 horses with red maple toxicosis and hemolysis had evidence of renal insufficiency, it was not an important risk factor for mortality.[19] Renal failure consequent to pigment nephropathy should be suspected in horses that become anorectic and more depressed during the week after an episode of tying-up or during a hemolytic crisis. Measuring serum activities of creatine kinase and aspartate aminotransferase may help confirm that ARF has developed in association with rhabdomyolysis. Because there is little preformed creatinine in muscle, rhabdomyolysis alone does not produce an increase in creatinine.[20]

34.2.2.1 VITAMIN K_3

Vitamin K_3 (menadione sodium bisulfite) was a common cause of ATN and ARF in certain parts of the United States before its withdrawal from the market. The development of ARF was thought to be idiosyncratic.[21]

34.2.3 Nonsteroidal Antiinflammatory Drugs

Most horses do not experience appreciable adverse effects from NSAIDs as long as they are administered at the proper dose and animals are not dehydrated. However, NSAID use may produce ARF in an occasional horse when excessive doses are administered or when dehydration is not corrected promptly.[22,23] The lesion produced by NSAID toxicity is medullary crest necrosis, which can be manifested by gross hematuria.[22–26] Unless severe, this lesion rarely causes overt clinical signs, and creatinine may actually decrease with fluid therapy in the face of medullary crest necrosis. An occasional horse may also develop chronic interstitial nephritis and nephrolithiasis after prolonged use (months to years) of NSAIDs at recommended doses.[27] Presence of concurrent gastrointestinal (GI) disease (ulceration) and protein-losing enteropathy would further support NSAID toxicity in both acutely and chronically affected horses.

When renal blood flow decreases because of dehydration or redistribution of cardiac output, counteracting vasodilatory mediators are produced and released within the kidney to attenuate the decrease in renal blood flow. The best studied of these vasodilatory mediators include renal prostaglandins (PGI_2 and PGE_2) and dopamine. Although the role of renal prostaglandins in control of basal renal blood flow is likely insignificant, renal prostaglandins are important mediators of vasodilation during periods of renal hypoperfusion.[28] Further, production of renal prostaglandins is several-fold greater in medullary tissue, such that action of these mediators leads to a greater increase in inner cortical and medullary blood flow. Thus, it should not be surprising that the lesion associated with NSAID toxicity is renal medullary crest necrosis (consequent to ischemia).[29] Similarly, it is important to remember that use of NSAIDs in dehydrated or hypovolemic patients increases the risk of acute nephrosis.[30]

34.2.4 Vitamin D

Vitamin D intoxication may result from ingestion of feed additives or plants (e.g., *Cestrum diurnum*) containing high amounts of vitamin D metabolites or parenteral administration of vitamin D.[31–33] Cholecalciferol (D_3) is thought to be more toxic in the horse than is ergocalciferol (D_2).[32] In general, horses do not need dietary supplementation with vitamin D as long as they are exposed to sunlight and have access to green forages. Further, because the effect of vitamin D supplementation is cumulative, signs of toxicity may not develop until several weeks after supplementation was started.

Clinical signs of vitamin D intoxication may be referable to the musculoskeletal, cardiovascular, or urinary systems.[33] Calcification of tendons and ligaments results in lameness, and calcification of cardiac muscle and great vessels can lead to cardiovascular problems. Mineralization of tendons and ligaments may be detected directly by palpation or indirectly through ultrasonographic imaging. Heart murmurs may accompany calcification of the great vessels, and ultrasonographic imaging of the heart and kidney may also reveal evidence of mineralization. Further clinical signs of renal toxicity include polyuria and weight loss.

Abnormal laboratory findings with vitamin D intoxication include azotemia, isosthenuria, hypochloremia, and elevations in both serum calcium and phosphorus concentrations. The latter combination of hypercalcemia and hyperphosphatemia is unusual for any other disease in the horse, although it may be seen with neoplasia on rare occasions. A definitive diagnosis of vitamin D toxicosis can be made by measuring serum concentrations of 25-OHD_3, 25-OHD_2, and 1,25-$(OH)_2$D. Treatment of vitamin D intoxication includes removal of the inciting cause (feed or medication), fluid diuresis, and corticosteroid administration. Provision of feeds low in both calcium and phosphorus may be of benefit in less severely affected horses, but treatment is usually unrewarding once clinical signs attributable to tissue mineralization have developed.

34.2.5 Heavy Metals

Accidental ingestion of heavy metals may result in ATN and ARF in horses. Mercury, cadmium, zinc, arsenic, and lead are all nephrotoxic but are rare causes of renal failure in the horse. Mercury has been used experimentally to study renal failure in horses,[34,35] and there are reports of ARF in horses that have had legs “blistered” or “sweated” with products containing inorganic mercury.[36,37] Because inorganic mercury also causes severe damage to intestinal mucosa, signs of GI irritation (e.g., increased salivation, oral erosions, colic, hemorrhagic diarrhea) predominate with mercury intoxication. Further evaluation may reveal oliguria. Exposure to excessive amounts of zinc and cadmium can result in nephrocalcinosis and renal failure, but gait deficits (resulting from osseous effects, particularly in foals) and ill-thrift are more likely presenting complaints than oliguria.[38]

926 927

Laboratory findings with heavy metal intoxication are characteristic for ATN (i.e., azotemia, isosthenuria to hyposthenuria, hyponatremia, hypochloremia). In horses with ARF concurrent with GI disease, as with mercury toxicity, severe hypocalcemia may be present. A tentative diagnosis of mercury intoxication may be made from history of exposure, clinical signs of erosive GI disease, and oliguric renal failure. The diagnosis can be confirmed by measuring increased blood and tissue (kidney and liver) concentrations of the metal. In addition to judicious fluid therapy, treatment of ARF induced by exposure to heavy metals should include dimercaprol, 3 mg/kg every 4 hours parenterally and 1 lb of charcoal orally. Visceral analgesics (flunixin meglumine) and sedatives (xylazine or detomidine) are often necessary to control abdominal pain.

34.2.6 Acorn Poisoning

Acorn poisoning is less common in equids than cattle (see Chapter 32), but it has been reported in horses.[39] Death in horses is usually the result of erosive GI disease, changes in vascular permeability, and resulting shock rather than a consequence of uremia. Immature leaves and green acorns are considered more toxic than mature acorns because the former have a higher tannin content. Clinical signs may include diarrhea, edema, and body cavity effusion, and laboratory evaluation usually reveals azotemia, isosthenuria to hyposthenuria, hyponatremia, and hypochloremia. Detection of increased urinary excretion of phenols may be useful to confirm the diagnosis.

34.2.7 Miscellaneous Drugs and Agents

Several other drugs and agents, particularly tetracycline, have been suspected of causing nephrotoxic ARF in horses.[40] When high doses of oxytetracycline (up to 70 mg/kg) are administered to neonatal foals for correction of limb contracture, ARF is a potential complication, especially if the foals are dehydrated or have concurrent sepsis or hypoxic-ischemic encephalopathy.[41] With renewed interest in polymyxin B as an adjunct treatment for endotoxemia, it is prudent to remember that this drug also has nephrotoxic potential. However, experimental studies have demonstrated that the risk of polymyxin B nephrotoxicity is low, especially when it is conjugated with dextran 70.[42] Amphotericin B also has considerable nephrotoxic potential, but it is rarely administered systemically to horses. Ochratoxins have potential to produce ATN, but ARF caused by ochratoxins has not been documented in horses. Similarly, pyrrolizidine alkaloid poisoning may cause renal disease in horses, but failure is unlikely. Blister beetle poisoning (cantharidin toxicosis) may cause abdominal pain, shock, hematuria, diaphragmatic flutter, dysuria, and renal dysfunction in horses fed alfalfa grown in regions where the beetles are prevalent.[43] One report of renal failure was associated with granulomas, as well as brain involvement, caused by the nematode *Halicephalobus*.[44]

34.2.8 Vasomotor Nephropathy

Any condition that causes sustained, marked hypotension or release of endogenous pressor agents can initiate hemodynamically mediated (vasomotor) ARF. Although poorly documented, vasomotor ARF may be more common than nephrotoxic ARF in the horse. Hemorrhagic shock, severe intravascular volume deficit (e.g., as with enterocolitis), septic shock, and coagulopathy are important risk factors for vasomotor ARF in horses.[45] Another cause may be adverse drug reactions, including those accompanying intravenous (IV) administration of vitamin and mineral products or immunomodulators. The predominant lesion in vasomotor nephropathy is ATN, although diffuse renal cortical or renal medullary necrosis may occur in some cases.

Clinical signs with vasomotor ARF are nonspecific and are more often referable to the primary disease (e.g., hemorrhage or diarrhea). Additional subtle signs, including more marked depression and anorexia than would be expected with the primary disease, with or without signs of mild colic, may increase suspicion of ARF. If sedation for colic signs is deemed necessary, xylazine or detomidine can be administered as long as intravascular volume and blood pressure are not overly compromised. Occasionally, horses with severe ARF may also be ataxic or manifest neurologic signs similar to hepatoencephalopathy.

Oliguria (often manifested as a lack of expected urination in response to fluid therapy) is an important early indicator of vasomotor ARF and production of dilute urine (specific gravity <1.020) that may be discolored (hematuria or hemoglobinuria) may be observed when urine is eventually voided. If urine produced is clear,

microscopic hematuria is usually present and will produce a positive result on reagent strip analysis of urine. Glucosuria may also be detected in an occasional horse with vasomotor ARF as a consequence of severe proximal tubular damage. Although the pathophysiologic relationship to ARF is not well defined, diarrhea and severe laminitis may develop in more serious cases of vasomotor ARF.

34.2.9 Acute Glomerulopathy

Although subclinical glomerular damage likely accompanies some diseases affecting horses, especially immune-mediated disorders (e.g., purpura hemorrhagica), acute glomerulonephritis is a rare clinical problem.[46] A syndrome of arteriolar microangiopathy and intravascular hemolysis causing distention of glomerular capillary loops with fibrin thrombi and accumulation of large amounts of proteinaceous debris in Bowman's capsule has also been described in a few horses.[47] Affected horses presented with oliguric ARF accompanied by hematuria, proteinuria, and intravascular hemolysis, and response to treatment was poor. The cause of the syndrome is not known, although renal lesions resemble those found with the hemolytic-uremic syndrome in humans (caused by toxins of *Escherichia coli*). Bacterial toxins, a consumptive coagulopathy, immune complex deposition, vasoactive amines, and hemodynamic alterations may all be contributors to this rare syndrome in horses.

Acute glomerulopathy should also be considered in horses with severe ARF that do not have a predisposing primary disease leading to vasomotor ARF and that have not been exposed to nephrotoxins. Gross hematuria, proteinuria, and oliguria would support an acute glomerulopathy, and renal biopsy can be pursued to confirm the lesion. Recently, in a case of toxic shock caused by *Streptococcus mitis,* ARF with glomerulopathy was one component of this syndrome.[48]

927

928

34.2.10 Acute Interstitial Nephritis

Acute interstitial nephritis is a rare syndrome of ARF accompanied by rapid elevations in creatinine and clinical signs of uremia. Renal lesions include interstitial edema with a mild inflammatory infiltrate. Although adverse drug reactions (idiosyncratic) may be a cause, the etiopathogenesis of this disease in horses is unknown. In humans, eosinophilic infiltrates in renal biopsy tissue are supportive of adverse drug reaction. Although there are no published reports of the syndrome in horses, I have examined three horses with apparent acute interstitial nephritis. Because of the pronounced interstitial edema that may accompany this disease, treatment with corticosteroids may be of benefit in suspect cases.

34.2.11 Leptospirosis

Acute renal failure attributable to infection with *Leptospira interrogans* serovar *pomona* has been documented in several foals and a stallion over the past decade.[49–52] Fever, partial anorexia, and depression were the presenting complaints, and gross hematuria was observed in one foal. Azotemia and low urine specific gravity (<1.020) without bacteriuria were common laboratory findings, although leptospiruria was detected in one foal. Leptospirosis should be included in the list of possible causes of ARF when an underlying primary disease leading to vasomotor nephropathy is not apparent and there has been no exposure to nephrotoxins. Seroconversion or high serum titers and positive fluorescent antibody test results on urine (air-dried sample on a microscope slide) can be used to establish the diagnosis. Successful treatment has been accomplished with IV fluids and penicillin administration.

34.3 DIAGNOSIS

Acute renal failure should be suspected in patients showing more marked depression and anorexia than would be expected with the primary disease process and in patients that fail to produce urine within 6 to 12 hours of initiating fluid therapy. Rectal palpation in horses with ARF may reveal enlarged, painful kidneys in some cases. Enlargement can be confirmed by renal ultrasonography, which may also reveal perirenal edema, loss of detail of the corticomedullary junction, or dilation of renal pelves.[53–55]

The diagnosis of ARF is confirmed on the basis of history, potential exposure to nephrotoxins, clinical signs, and laboratory findings. The increase in creatinine is often several-fold greater (e.g., up to 5 to 15 mg/dL) than for blood urea nitrogen concentration (BUN) (e.g., up to 50 to 100 mg/dL) resulting in a BUN/creatinine ratio that is often less than 10:1. Hyponatremia, hypochloremia, and hypocalcemia are usually present, and in more severe cases, hyperkalemia, hyperphosphatemia, and metabolic acidosis may also be detected.

In addition to assessment of the magnitude of azotemia and alterations in serum electrolyte concentrations and acid-base balance, urinalysis should be performed on all horses in which ARF is suspected. As mentioned previously, a low urine specific gravity (≤1.020) in the face of dehydration and gross or microscopic hematuria are common findings with ARF. In addition, evidence of more substantial proximal tubular damage, including increased urinary enzyme activity and glucosuria, may be detected in some horses, and significant proteinuria (urine protein/creatinine ratio >2:1; see Chronic Renal Failure) would support glomerular disease. Examination of urine sediment may reveal casts and increased numbers of erythrocytes and leukocytes, and the amount of urine crystals may be decreased. Increased fractional clearances of sodium and phosphorus are also common findings with ARF. It is important to remember that administration of IV fluids to healthy horses will also result in increased fractional clearances of sodium, chloride, and phosphorus.[56] Thus, electrolyte clearances are ideally determined using the initial urine sample voided after admission or a sample collected by catheterization (i.e., before urine substantially altered by fluid therapy).

The most accurate assessment of renal function involves measurement of glomerular filtration rate (GFR). GFR can be determined by performing timed urine collections (inulin and endogenous or exogenous creatinine clearances) or by assessing plasma disappearance of several compounds (sodium sulfanilate, phenolsulfonphthalein, or radiolabeled substances).[57] In a clinical setting, measurement of GFR in cases of ARF is rarely pursued because multiple measurements are required to assess changes in GFR, and prognosis for recovery is more likely related to the duration of decreased GFR rather than the magnitude of the decrease. Further, because of the inverse relationship between GFR and creatinine, changes in GFR can be more practically assessed by daily creatinine measurement.

Glomerular injury and tubular necrosis can be further confirmed by performing a renal biopsy. However, biopsy is rarely indicated in cases of ARF because the diagnosis is usually evident. Further, correlation between light microscopic findings and functional changes in animals with ARF has not been well established; thus, prognosis often depends more on response to treatment than results of renal biopsy. Immunofluorescent (IF) testing and electron microscopic (EM) examination are routinely performed on human renal biopsy samples to assess mechanisms of renal injury and extent of damage to glomerular and tubular basement membranes. If such detailed evaluation of renal biopsy tissue were also performed in horses with ARF, better information regarding etiopathogenesis and prognosis would likely be provided by the pathologist.

At present, renal biopsy is most often indicated in the evaluation of horses with ARF for which exposure to nephrotoxins or another underlying primary disease process is not apparent. However, renal biopsy should be

approached cautiously because life-threatening hemorrhage is a potential complication. Biopsy of the right kidney with ultrasonographic guidance, usually through the seventeenth intercostal space, is the preferred procedure for renal biopsy.[58] Use of proper instrumentation (automatic or spring-loaded biopsy instruments) and adequate restraint (stocks and sedation) are important considerations. Renal tissue collected should be placed in formalin for histopathologic examination as well as frozen (or placed into additional media specified by the testing laboratory) for IF testing and EM examination. Although biopsy of the right kidney alone usually is adequate for assessment of the disease process affecting both kidneys, samples of the left kidney can also be collected by guiding the biopsy instrument through the spleen. Again, ultrasonographic guidance is important when collecting a biopsy from the left kidney or when biopsy of a specific area of either kidney is desired.

34.4 GENERAL PRINCIPLES OF TREATMENT

General principles of treatment of ARF in the horse are similar to those recommended for human patients.[59,60] Initial treatment should always focus on judicious fluid therapy to replace volume deficits and correct electrolyte and acid-base abnormalities. The magnitude of azotemia and serum concentrations of sodium, chloride, potassium, and bicarbonate should be monitored daily. Sodium and chloride replacement are often required in horses with polyuric ARF and can be accomplished by using 0.9% NaCl as the fluid administered or through electrolyte supplementation in grain feedings or as oral pastes. Serum potassium concentration in horses with nonoliguric ARF is often normal, and except for postrenal problems (e.g., obstruction or rupture), therapy intended to lower serum potassium is usually not necessary. Similarly, it is usually unnecessary to correct the mild hypocalcemia that can accompany ARF in horses.

928

929

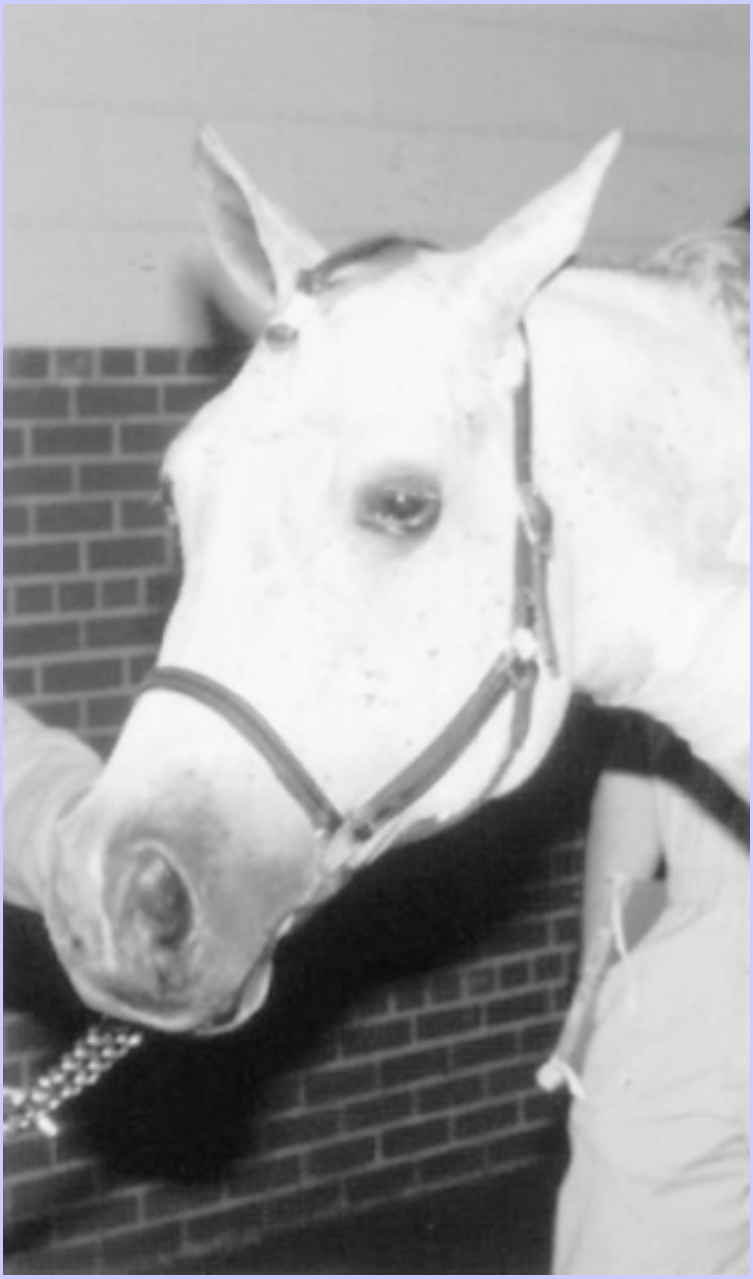
After correction of volume deficits and electrolyte and acid-base abnormalities, an attempt should be made to determine if the animal is oliguric or nonoliguric (polyuric) because the prognosis for recovery appears to be more favorable with nonoliguric ARF. This often becomes apparent by simple observation: oliguric horses fail to produce expected amounts of urine in the initial 12 to 24 hours of IV fluid therapy, and the bedding remains dry, whereas nonoliguric horses repeatedly void moderate volumes of dilute urine during the initial 6 to 12 hours of treatment. Further, edema can develop rapidly in horses with oliguric ARF. In horses with prerenal azotemia rather than intrinsic ARF, creatinine should decrease by at least 30% to 50% within the initial 24 hours of fluid therapy. In contrast, creatinine remains unchanged, or may even increase, with ARF.

In severely ill patients, especially those with vasomotor nephropathy, systemic blood pressure (BP) can be monitored to confirm that fluid therapy has been adequate to restore BP. Some horses may remain hypotensive (systolic BP <80 mm Hg) despite administration of large volumes of IV fluids because fluid may be accumulating extravascularly as edema or a third space fluid. If systemic BP remains low, hypertonic saline, dobutamine, or other pressor agents may be needed to restore BP and glomerular filtration. Fluid and sodium replacement in horses with oliguric renal failure and normal systemic BP must be monitored closely because, as previously mentioned, overzealous fluid administration to horses with oliguric or anuric ARF will result in edema formation, which is often initially noticed in the conjunctiva (Fig. 34-1).

In addition to regular assessment of attitude, vital parameters, packed cell volume, and total plasma protein concentration, monitoring should also include measurement of body weight once or twice daily (patients should not gain weight after rehydration) and comparison of fluid input with fluid (urine) output. Although there is no convenient method of collecting all urine voided by ambulatory foals or mares, urine output can be rather easily quantified in male horses by placing a urine collection device around the abdomen.[61] When desired, monitoring urine output in critically ill foals and mares can be accomplished by use of an indwelling Foley catheter and urine collection bag (closed system), but ascending infection is a risk. Finally, central venous pressure (CVP) can also be

monitored as a more precise measure of fluid balance in critical patients. CVP is measured with a manometer, with the baseline at the level of the right atrium, attached to an IV catheter placed into the anterior vena cava via the jugular vein (normal CVP in horses, <8 cm H_2O).

Fig. 34-1 Severe conjunctival edema from intravenous (IV) fluid therapy in a 3-year-old Arabian with oliguric acute renal failure (ARF). The ARF and a multifocal granulomatous pneumonia occurred after IV administration of an approved immunomodulator.



In horses that remain oliguric after 12 to 24 hours of appropriate fluid and electrolyte replacement and restoration of systemic BP, furosemide at 1 mg/kg intravenously [IV] every 2 hours should be administered. Unfortunately, furosemide treatment is often ineffective in increasing renal blood flow, GFR, and tubular flow in horses with ARF.[60,62] Continuous infusion of furosemide at 0.12 mg/kg/hr, preceded by a loading dose of 0.12 mg/kg IV, was considered superior to intermittent use in one study.[63] If urine is not voided after the second dose, administration of mannitol (1 mg/kg as a 10% to 20% solution) and/or a dopamine infusion (3 to 7 µg/kg/min IV) can be instituted. Dopamine administration should only be performed in a hospital setting in which heart rate and BP can be monitored frequently to avoid development of tachycardia and hypertension. Use of dopamine for selective renal vasodilatory and natriuretic actions has recently been called into question because most studies in humans have not demonstrated prevention of ARF in high-risk patients or improved outcome in those with established ARF.[64] Further, the drug may precipitate serious cardiovascular and metabolic complications in critically ill patients. If these treatments are successful in converting oliguria to polyuria (may require 24 to 72 hours), they can be discontinued, but maintenance of urine production must be monitored closely over the next few days. Fortunately, the majority of horses with ARF resulting from ATN are nonoliguric rather than oliguric, and administration of furosemide, mannitol, or dopamine is not needed in most of cases of nonoliguric ARF.

When this treatment approach to oliguria remains unsuccessful for more than 72 hours, the prognosis becomes grave. One study of horses with colic or colitis found that horses with persistent azotemia after 72 hours of fluid therapy were three times as likely to die or be euthanized as the horses without persistent azotemia.[65] However, dialysis therapy may be a further treatment option in select patients. Hemodialysis has been successfully used to treat two adult horses with myoglobinuric ARF[66,67] and a neonatal foal with oxytetracycline-induced ARF.[41] Peritoneal dialysis has been attempted in a few horses with nephrotoxic-induced ARF; however, omental plugging of the catheter has limited its success, and special dialysis catheters are needed for effective fluid exchange. Pleural dialysis is another option for which fluid exchange is less problematic. Hemodialysis or dialysis would likely be most effective in horses with nephrotoxic ARF, whereas vasomotor nephropathy is best treated by addressing the predisposing condition and instituting appropriate fluid therapy.

After volume deficits have been restored and polyuria has been achieved, patients usually require only continued fluid therapy (0.9% NaCl or another balanced electrolyte solution, 40 to 80 mL/kg/day) to promote a continued decrease in creatinine. Fluid therapy may need to be continued (20 to 40 mL/kg/day) for several days until creatinine returns to the normal range or a steady-state value and the horse is eating and drinking adequate amounts. Supplementation with oral electrolytes (1 to 2 oz NaCl twice daily) will also promote greater fluid intake and diuresis. Potassium supplementation (1 oz KCl twice daily) may also be required because the diuresis also results in kaliuresis. When horses remain anorectic during treatment, addition of 50 to 100 g dextrose/L fluids can provide needed calories, and if anorexia persists for several days, caloric intake may need to be provided by nasogastric tube feeding or total parenteral nutrition.

929

930

Within the week after fluid therapy is discontinued, creatinine should be measured again to ensure that it has not increased. Occasionally, creatinine may not decrease to below 2 to 3 mg/dL despite continued fluid therapy. As long as the horse is eating and drinking well, IV fluids can be discontinued. In some horses, further recovery will be manifested as a return of creatinine to the normal range within the next couple of months, whereas in other patients a persisting elevation in creatinine indicates a permanent loss of renal function.

34.5 CHRONIC RENAL FAILURE

THOMAS J. DIVERS

Chronic renal failure (CRF) in the horse may be divided by clinical and pathologic findings into two broad categories: primary glomerular disease and primary tubulointerstitial disease.[68,69] However, pathology in one portion of the nephron usually leads to altered function and eventual pathology in the entire nephron. Thus, CRF is an irreversible disease process characterized by a progressive decline in GFR. However, the rate of decline in GFR is variable between affected horses, making the short-term (e.g., months to 2 years) prognosis guarded to favorable while the long-term prognosis remains poor.

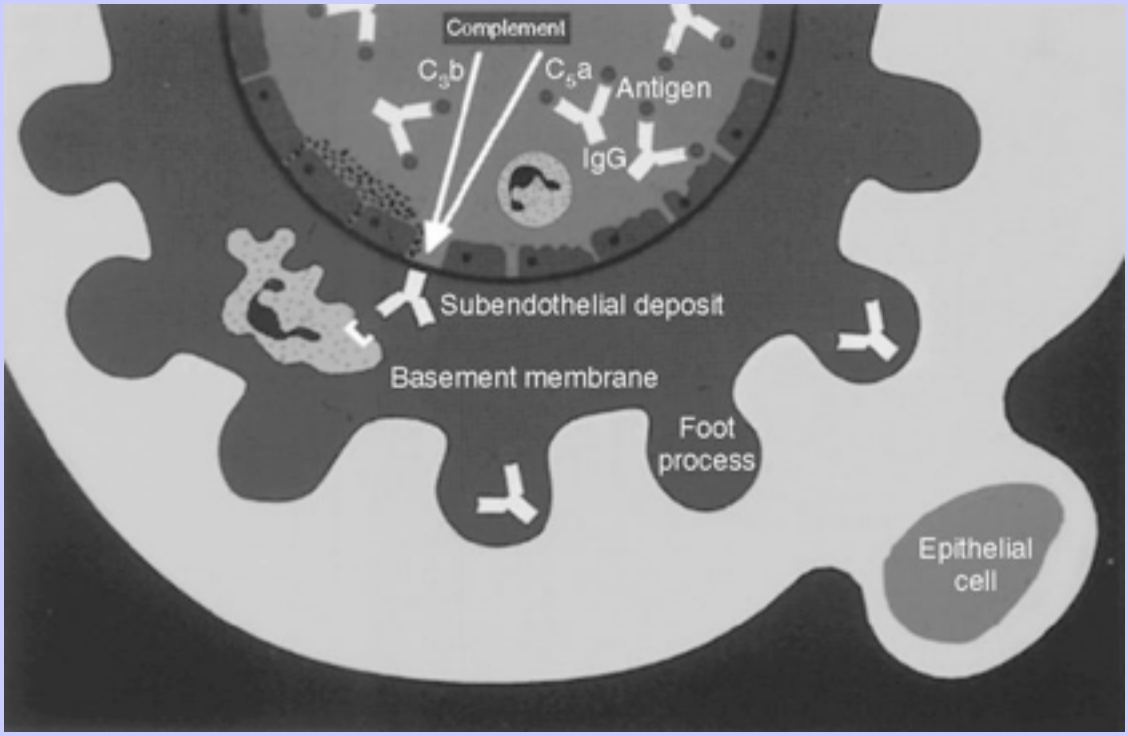
Primary *glomerular* diseases that can lead to CRF in horses include glomerulonephritis, nonspecific glomerulopathy, renal glomerular hypoplasia, and amyloidosis. Primary *tubulointerstitial* diseases causing CRF include incomplete recovery from acute tubular necrosis (ATN), pyelonephritis, nephrolithiasis, hydronephrosis, renal dysplasia, and rarely, papillary necrosis. Collectively, the latter disorders produce pathology categorized as *chronic interstitial nephritis*. Unfortunately, because renal disease is often advanced when horses are first presented for clinical evaluation, the inciting cause leading to CRF may be difficult to ascertain, and end-stage kidney disease (ESKD) may be the pathologic diagnosis. The inciting cause may more likely be discerned from the history (long term) rather than clinical findings at presentation, especially for primary tubulointerstitial diseases. Adjunctive diagnostic evaluation, including laboratory assessment, renal ultrasonography, and renal biopsy, may provide further evidence to document the inciting cause.

34.6 CAUSES

34.6.1 Proliferative Glomerulonephritis

Proliferative glomerulonephritis (GN), indicating increased cellularity of the glomerular tufts consequent to influx of inflammatory cells and proliferation of mesangium, is the most common glomerular disease causing CRF in horses. It is thought to result from deposition of circulating immune complexes along the glomerular capillaries or in situ formation along the glomerular basement membrane (GBM) (Fig. 34-2). Deposition of immune complexes causes activation of complement and vasculitis (type III hypersensitivity response). In one study, deposits of immunoglobulin G (IgG) and complement along the GBM were found through immunofluorescent (IF) staining in a large percentage (22 of 53) of horses at necropsy.[70] However, only 1 of these 53 horses developed CRF. Thus, although immune (antigen-antibody) complex deposition and subclinical GN may be common in horses, progression to CRF appears to be an infrequent occurrence. In this necropsy survey the predominant IF staining pattern was granular (patchy deposits of immune complexes and complement along GBM), but linear deposits were found in two horses. The latter finding was supportive of true autoimmune disease with more diffuse deposition of anti-GBM antibodies (type II hypersensitivity response) along the basement membrane antibody.

Fig. 34-2 Depiction of a subendothelial immunologic reaction suspected to occur in horses with streptococcal antigen-antibody—associated glomerulonephritis.



Streptococcal antigens have been suggested to be an important trigger for development of proliferative GN,[71] and in one horse with CRF, streptococcal antigens were confirmed to be present in diseased glomeruli.[72] Although equine infectious anemia virus is the only other antigen that has been detected in glomeruli of horses with proliferative GN,[73] subclinical GN likely accompanies other chronic infections in horses. It has also been suggested that equine GN may also be associated with either mixed or monoclonal cryoglobulins forming antibody-antibody glomerular depositis.[74] Fortunately, GN in most patients is rarely of clinical significance.

34.6.2 Chronic Interstitial Nephritis

Chronic interstitial nephritis (CIN) and fibrosis may be the most common cause of CRF in horses. Interstitial nephritis (tubulointerstitial disease) usually develops as a sequela to ATN consequent to exposure to nephrotoxins or vasomotor nephropathy. Other causes include drug-induced interstitial nephritis, urinary obstruction, pyelonephritis, renal hypoplasia/dysplasia, and papillary necrosis. Although the majority of horses that develop ARF attributable to these causes recover with apparently normal renal function (they remain nonazotemic), a few may survive with significant loss of renal functional mass and subsequently (often years later) develop signs of CRF attributable to CIN.[75] In horses less than 5 years of age that develop CRF that cannot be attributed to other causes, anomalies of development, including renal hypoplasia, dysplasia, and polycystic kidney disease, should be strongly suspected[69,76–78] (Fig. 34-3).

Fig. 34-3 Yearling thoroughbred with chronic renal failure caused by renal dysplasia. Failure to grow normally and lethargy were the primary complaints.

34.6.3 Pyelonephritis

Bilateral septic pyelonephritis is a rare cause of CRF in horses.[79–81] Pyelonephritis is usually a result of an ascending infection and is often accompanied by nephrolithiasis or ureterolithiasis. Multiparous mares, especially those with a history of dystocia, and horses with bladder paralysis are at greater risk for bacterial colonization of the lower urinary tract and subsequent development of ascending infection. Chronic distention with bladder paralysis compromises the integrity of the ureteral orifices, leading to vesiculoureteral reflux and pyelonephritis. With long-standing bladder paralysis, the ureteral orifices may appear wide open during cytoscopic examination, and in an occasional affected horse, the endoscope can be advanced into the ureter with little resistance. With unilateral pyelonephritis, adequate renal function is usually maintained by the contralateral kidney; however, passage of small uroliths into the bladder can lead to recurrent urethral obstruction. Gram-negative organisms appear to be the most common causative agents, although *Staphylococcus, Streptococcus,* or *Corynebacterium* species may be isolated in some cases, and mixed bacterial infections are not uncommon.

34.6.4 Miscellaneous Causes

Other reported causes of CRF in horses include amyloidosis,[82] neoplasia,[83] focal glomerulosclerosis-like disease,[84] and chronic oxalate nephrosis.[85] One study described CRF caused by polycystic kidney disease in an aged pony with hematuria, which also had hepatic cysts.[86] Renal amyloidosis has been reported only in horses used for production of antiserum.[82] Further, “oxalate nephropathy” in horses is likely a misnomer because the presence of oxalate crystals in renal tissue of horses with CRF is typically a consequence, rather than the cause, of CRF.[85]

34.7 Clinical Signs and Laboratory Findings

The most common clinical sign observed in horses with CRF is weight loss.[69] A small plaque of ventral edema, usually between the forelimbs, is another frequent finding in horses with CRF.[69,87] Moderate polyuria and polydipsia (PU/PD) are usually present at some stage of the disease process, but PU/PD may not be noticed except by the astute owner or trainer.[69] Dysuria is generally not reported unless CRF is caused by pyelonephritis, which may be associated with bladder paralysis, lithiasis, and lower urinary tract infection (UTI). Normal equine urine is rich in crystals and mucus, making a prediction of urine abnormalities on gross observation difficult. However, hematuria or pyuria (gross or microscopic) may be reported in some, but not all, horses with pyelonephritis, urinary calculi, or neoplasia. Often, urine produced by horses with CRF is light yellow and transparent because it is relatively devoid of crystals and mucus. Accumulation of dental tartar, especially on the incisors and canine teeth (Fig. 34-4); melena; and oral ulcers are other findings that may be detected in horses with CRF. Growth in horses with renal hypoplasia, dysplasia, or polycystic kidney disease may be stunted. Although abdominal pain would be expected in horses with obstructive nephroliths or ureteroliths, colic signs are not often reported in horses with lithiasis producing obstruction of the upper urinary tract.[75,88]

Clinicopathologic findings in horses with CRF vary depending on appetite, diet, and the cause and severity of renal damage. Most horses with clinical signs of CRF have moderate to severe azotemia (creatinine usually ≥5 mg/dL). The BUN/creatinine ratio may vary, depending on protein intake, muscle mass, hydration, and degree of azotemia, but is usually 10:1 or greater. Mild hyperkalemia, hyponatremia, and hypochloremia are typically found in horses with CRF. Hypercalcemia, with serum concentrations sometimes exceeding 20 mg/dL, appears to be a laboratory

finding with CRF that is unique to the equid. One early case series of CRF reported six of nine horses to be hypercalcemic[89]; however, others have found a lower percentage to be hypercalcemic.[90] Hypercalcemia in horses with CRF is not a consequence of hyperparathyroidism,[91] and its presence or absence appears to be more closely related to dietary intake than to the magnitude of azotemia. For example, four of four nephrectomized ponies fed alfalfa hay developed marked hypercalcemia,[92] whereas serum calcium concentration remained within the normal range in four of four nephrectomized ponies fed grass hay (although filterable calcium did increase).[68] Similarly, hypercalcemia in horses with spontaneously occurring CRF can resolve within a few days of changing diet from alfalfa to grass hay.[78] Serum phosphorus concentration in horses with CRF is usually normal to decreased, and hypophosphatemia is more often detected with concurrent hypercalcemia. Hypermagnesemia may also be detected in some horses with CRF. Acid-base balance usually remains normal until CRF becomes advanced, but metabolic acidosis is a common finding in horses with end-stage disease.

931

932

Fig. 34-4 Dental tartar caused by chronic azotemia in a 5-year-old standardbred with chronic renal failure.

Many horses with CRF are moderately anemic (packed cell volume, 20% to 30%) as a consequence of decreased erythropoietin production by the diseased kidneys. Those with CRF resulting from GN frequently have hypoalbuminemia and hypoproteinemia, and horses with advanced CRF of any cause may also have mild hypoproteinemia associated with intestinal ulceration. Hyperglobulinemia may be detected in horses with immune-mediated diseases or chronic pyelonephritis. Horses with CRF can also develop hypercholesterolemia and hypertriglyceridemia (hyperlipidemia), and a horse with advanced CRF occasionally may have grossly lipemic plasma.[93]

Urinalysis findings may also vary depending on the cause of CRF. As mentioned, urine collected from horses with CRF is relatively devoid of normal mucus and crystals, making samples transparent. Further, urine specific gravity is typically in the isosthenuric range (1.008 to 1.014), although heavy proteinuria in an occasional horse with GN may produce values up to 1.020. Quantification of urine protein concentration (as for cerebrospinal fluid) is required to assess proteinuria accurately. Urine protein concentration in normal horses is usually less than 100 mg/dL, and the urine protein/creatinine ratio should be less than 1:1.[94,95] With significant proteinuria, urine protein/creatinine ratio is usually greater than 2:1.[72] In the earlier stages of GN, excessive urine protein is primarily albumin, but with progression of glomerular pathology, an increasing amount of globulin is also lost in the urine. Horses with CIN usually do not have significant proteinuria. Hematuria (gross or microscopic) may be present with pyelonephritis, urinary calculi, or neoplasia and can produce trace proteinuria, but urine protein/creatinine ratio usually remains less than 2:1. Although horses with septic pyelonephritis would be expected to have pyuria (>5 leukocytes/high-power field) and significant bacteriuria on sediment examination, these findings are not consistently detected, and a urine sample should be submitted for quantitative bacterial culture in all horses with CRF. Usually, more than 10,000 colony-forming units per milliliter of urine are found with infection, although lower numbers do not always rule out septic pyelonephritis.

34.8 Diagnosis

A diagnosis of CRF is most often made in horses with azotemia and isosthenuria that present with a complaint of weight loss or decreased performance. As discussed earlier, determining the inciting cause of CRF can be difficult because the disease has often advanced to ESKD when horses are initially presented for evaluation. Urinalysis does not often reveal the cause of CRF, except in some horses with pyelonephritis. In theory, assessment of urine protein concentration and urine protein/creatinine ratio should be helpful in separating glomerular disease from tubulointerstitial disease, but in practice, these laboratory measures have not consistently been elevated in horses with histopathologic evidence of glomerulonephritis. However, detection of moderate to heavy proteinuria (urine protein/creatinine ratio >2:1) without hematuria provides support for glomerular disease.

Rectal examination may be helpful in determining the cause of CRF. Horses with pyelonephritis, as well as those with ureteral calculi, often have enlarged ureters that can be palpated dorsolaterally as they course through the retroperitoneal space. Although kidneys of horses with CRF are often small with an irregular surface, these changes are not always apparent on palpation of the caudal pole of the left kidney. The right kidney cannot usually be palpated in the horse unless it is greatly enlarged or displaced caudally by the liver or a mass. Ultrasonographic imaging is useful for evaluating kidney size and echogenicity and may reveal fluid distention (hydronephrosis, pyelonephritis, polycystic disease) or presence of nephroliths.[96–98] Horses with significant renal parenchymal damage and fibrosis often have loss of detail of the corticomedullary junction, and echogenicity of renal tissue may be similar or even greater than that of the spleen. In contrast, intravenous pyelography (IVP) provides little information in adult horses and its use is generally limited to foals less than 50 kg. When hematuria or dysuria accompanies CRF, cystoscopic examination can be helpful in determining the side (right vs. left) from which renal hematuria is originating and further allows assessment of the ureteral orifices and urine flow from each kidney.

As described under Acute Renal Failure, measurement of GFR provides the most accurate assessment of renal function, and repeated measurements at monthly or longer intervals can be useful to monitor rate of progression of CRF. It is also a useful measure to document a reduction in renal function in horses that are thought to have early CRF, before significant azotemia has developed. GFR can be measured by several methods, including urinary clearance of endogenous or exogenous creatinine, inulin, or technetium-99m diethylenetriamine pentaacetic acid (^{99m}Tc-DTPA) (all require timed urine collections) or plasma disappearance of sodium sulfanilate,

phenolsulfonphthalein, or radiolabeled compounds (e.g., ^{99m}Tc-DTPA).[78,99–102] Assessment of renal function by nuclear scintigraphic imaging of the kidneys has also been described, but in horses this technique appears to be better for documenting decreased individual kidney function (i.e., with unilateral or asymmetric disease) than for quantitative assessment of GFR.[103,104] In most clinical settings, performing a 24-hour endogenous creatinine clearance is the most practical and economical method for measuring GFR. The major challenge is application of a urine collection device for collection of all urine produced. Once urine has been collected, a well-mixed sample is submitted to the laboratory, along with a sample of serum obtained during the collection period, and GFR is estimated by the following standard clearance formula:

$$\mathrm{GFR\,(mL \cdot kg^{-1} \cdot min^{-1})} = \left\{ \left([\mathrm{Cr}_{urine}] \Big/ [\mathrm{Cr}_{serum}] \right) \times \mathrm{UF} \right\} \Big/ \mathrm{bwt}$$

where *UF* is urine flow (mL • min^{-1}) and *bwt* is body weight in kilograms.[100] GFR in horses with normal renal function ranges from 1.5 to 3.0 mL • kg^{-1} • min^{-1}, and values less than 1.0 mL • kg^{-1} • min^{-1} are indicative of a decrease in GFR. Although repeated measurement of endogenous creatinine clearance provides useful information about the rate of decline in GFR in horses with CRF, simply measuring creatinine and assessing body condition at monthly or longer intervals are the most common methods used to evaluate the progression of CRF in affected horses.

The inciting cause of CRF can be confirmed in some horses by renal biopsy. As discussed under Acute Renal Failure, renal biopsy should be approached cautiously and pursued only if findings are likely to change treatment or prognosis. Treatment for CRF consists of supportive care, and the long-term prognosis is poor; therefore, renal biopsy is rarely indicated in horses with CRF. Further, most horses have rather advanced CRF at the time the disease is initially detected, and biopsy results in these patients may not provide useful information regarding the inciting cause.

34.9 Treatment

Treatment of horses with CRF is most likely to produce improved renal function if there is an acute, reversible component exacerbating CRF (i.e., acute on chronic syndrome). Similar to ARF, sudden exacerbation can be caused by exposure to nephrotoxins or vasomotor nephropathy secondary to diseases producing hypovolemia (e.g., diarrhea or sepsis causing volume depletion). Ascending urinary tract infection or obstruction can also exacerbate CRF. If an acute component is detected, it should be corrected rapidly (as described for ARF) with the goal of minimizing further loss of functional nephrons. In addition, surgical removal or fragmentation of stones may be indicated in horses with calculi thought to be disrupting urine flow.

932 933

In horses with relatively stable CRF, management changes should be kept to a minimum and, when necessary, made gradually. Treatment of horses with stable CRF consists of supportive care: providing sufficient fluids, electrolytes, and nutritional support.[105] Water should be available at all times, and salt can be provided freely as long as edema or hypertension is absent. If edema develops, salt should be restricted, even in the face of hyponatremia. In addition to creatinine, serum electrolyte concentrations and acid-base balance should be measured regularly (e.g., monthly or longer intervals). If serum sodium and chloride concentrations are decreased, 60 to 120 g (~2 to 4 oz) of salt may be added to the feed, provided edema is not present. If metabolic acidosis is detected (e.g., blood pH <7.35 or serum bicarbonate concentration <20 mEq/L) and the patient is not edematous, sodium bicarbonate ($NaHCO_3$) powder (100 to 200 g/day) or a mix of $NaHCO_3$ and salt should be added to the diet. The goal of supplementation with salt and $NaHCO_3$ is to maintain serum electrolyte concentrations and acid-base balance within reference ranges. However, the effect of electrolyte supplementation on progression of CRF is

unclear because high-salt diets may actually hasten the decline in GFR and exacerbate proteinuria in human patients with CRF.[106]

Although no adverse effects of hypercalcemia in horses with CRF have been documented, decreasing calcium intake (e.g., replacing alfalfa or other legume hays with grass hay) may result in a return of serum calcium concentration to the normal range. The hypophosphatemia that usually accompanies hypercalcemia in horses with CRF may prevent mineralization of soft tissues. There appears to be no need for vitamin D supplementation in horses with CRF but regular administration of vitamin B complex, and anabolic steroids may be helpful to stimulate appetite. If appetite remains good, anabolic steroids may further limit muscle wasting and may increase packed cell volume (PCV). Attenuation of anemia in human and canine patients with CRF by administration of recombinant erythropoietin has been one of the most significant advances in management of CRF because it has eliminated the need for blood transfusions, improved exercise capacity, and decreased morbidity associated with the uremic syndrome.[107] In an occasional horse with advanced CRF, marked hyperlipemia may develop, and administration of heparin (40 to 100 IU/kg subcutaneously [SC] twice daily) may stimulate lipoprotein lipase and decrease plasma triglyceride concentration.[108] However, this treatment is not without risk because it may cause a further decline in PCV and potentiate bleeding tendencies in a uremic patient. NSAIDs and corticosteroids are best avoided in horses with CRF attributable to primary tubulointerstitial disease. If these drugs are essential for treatment of a complicating problem, they should be used judiciously.

Treatment of CRF consequent to GN appears to be even less rewarding than treatment of CRF caused by tubulointerstitial disease (CIN). Immunosuppressive therapy has been of limited benefit in slowing the progression of the disease and may even hasten weight loss. For patients with significant edema, treatment with diuretics may result in transient improvement, and plasma transfusions may be of temporary benefit to horses with edema and hypoalbuminemia.

As CRF progresses, partial anorexia and lethargy lead to more rapid loss of body condition. Thus, nutritional management aimed at maintaining body condition is probably the most important aspect of supportive care of horses with CRF. Increasing carbohydrate (grain) intake and adding fat to the diet are recommendations to increase caloric intake. Fat can be added by feeding corn oil (up to 16 oz/day) or a commercial fat supplement. Increased intake of omega-3-fatty acids (e.g., available in linseed oil or flaxseed oil) has been demonstrated to slow the progression of renal failure in experimental models, but potential benefits in spontaneously occurring CRF are less clear.[109,110] Over the past two decades, restricting dietary protein intake by human and veterinary patients with CRF was thought to have beneficial effects[111]; however, the current recommendation is to provide adequate amounts of dietary protein and energy to meet or slightly exceed predicted requirements while maintaining a neutral nitrogen balance.[112] In horses with CRF, adequacy of dietary protein intake can be assessed by the BUN/creatinine ratio; values greater than 15:1 suggest excessive protein intake, and values less than 10:1 may indicate protein-calorie malnutrition. Finally, an important but often overlooked aspect of nutritional management of horses with CRF is provision of a highly palatable diet. Feeding smaller meals more frequently and varying the diet (e.g., offering various types of concentrate feeds as appetite may vary from day to day) are helpful methods to increase food intake.

Additional treatments for CRF in human patients include antihypertensive agents including diuretics, β-adrenergic blockers, and angiotensin-converting enzyme (ACE) inhibitors.[113] Use of ACE inhibitors may have an additional benefit of limiting proteinuria.[114] Currently, little is known about the roles of systemic or intrarenal hypertension in progression of renal disease in horses, and there are no reports of potential benefits of use of antihypertensive medications in horses with CRF. Finally, efforts are under way to examine the roles of mediators of inflammation

in development of renal fibrosis, with the hope that future specific interventions may be developed to limit the progressive interstitial fibrosis that occurs in all patients with CRF.[115]

Horses with end-stage CRF often develop oliguria and uncontrollable metabolic acidosis. At this stage, CRF can only be managed by hemodialysis or peritoneal/pleural dialysis. However, pursuit of either hemodialysis or peritoneal dialysis in horses with CRF is impractical because, even when successful, dialysis prolongs the life of the patient for only a short time.

34.10 Prognosis

The progressive loss of nephron function that is characteristic of CRF precludes successful long-term treatment in horses. However, many horses with early CRF may be able to continue in performance or live as a pet for months to a few years. In general, as long as creatinine remains less than 5.0 mg/dL and the BUN/creatinine ratio is less than 15:1, affected horses seem to maintain a reasonably good attitude, appetite, and body condition. However, once creatinine exceeds 5.0 mg/dL, the rate of progression of CRF appears to accelerate, and signs of uremia (e.g., anorexia, poor hair coat, loss of body condition) become more apparent over a few weeks to months. Although this threshold value for creatinine is a useful figure for offering an initial prognosis for most horses with CRF, it is important to remember that progression of CRF is highly variable between affected animals. Thus, each case must be handled on an individual basis, with the emphasis on maintenance of body condition until humane euthanasia may become necessary.

34.11 URINARY TRACT INFECTIONS

THOMAS J. DIVERS

Urinary tract infections (UTIs) can be anatomically divided into two categories: (1) those affecting the upper urinary tract (kidneys and ureters) and (2) those involving the lower urinary tract (bladder and urethra). Lower UTI in horses usually results from anatomic or functional causes of abnormal urine flow, especially bladder paralysis (see Urinary Incontinence). Although recognized less frequently, upper UTI is often a more serious, potentially life-threatening problem. In horses, UTI is also frequently accompanied by urolithiasis and partial obstruction. With the exception of single, large cystoliths (that predispose affected horses to lower UTI), it is often difficult to determine whether development of nephroliths, ureteroliths, multiple small cystoliths, and urethroliths was a predisposing cause or a consequence of UTI. The pathophysiology, diagnosis, and management of equine UTI has recently been extensively reviewed.[116]

34.12 RISK FACTORS AND CAUSES

The most common risk factors for development of UTI in horses are bladder paralysis, concurrent urolithiasis, and urethral damage (e.g., foaling trauma in mares, neoplasia or habronemiasis in stallions and geldings). The shorter urethra and its location near the anus also increase the risk of lower UTI in healthy females. For example, silent lower UTIs and pyelonephritis, resulting from infection with bacteria shed from the GI tract, can develop in prepubertal girls and during pregnancy or after menopause in adult women.[117] This increased risk at certain times in women has been further attributed to a lack of estrogen, a hormone that appears to be important for production of glycosaminoglycans that cover uroepithelial surfaces and inhibit attachment of bacteria.[118] Whether fillies or pregnant mares are at increased risk for UTI has not been studied. However, horses with bladder paralysis (detrusor dysfunction) or decreased urethral sphincter tone (from trauma or neurologic disease) are clearly at greater risk of

UTI than horses with normal detrusor and urethral sphincter function. Finally, because bladder catheterization cannot be performed in a sterile manner because of normal bacterial flora in the vestibule and distal urethra, contamination of the lower urinary tract is an accepted risk of this procedure. Nevertheless, development of lower UTI is an unlikely complication of bladder catheterization in otherwise healthy animals because host defense mechanisms, including urine flow, are highly effective in eliminating contaminating bacteria. However, when urethral or bladder mucosa has been damaged or when urine stasis (bladder paralysis) is present, bladder catheterization has a greater risk of producing UTI.

In a group of horses with neurologic bladder dysfunction complicated by UTI, *Escherichia coli, Staphylococcus* species, *Corynebacterium* species, and *Pseudomonas aeruginosa* were the microbes isolated most frequently.[119] In my experience, *E. coli, Proteus mirabilis, Klebsiella* species, and *Enterobacter* species are the most common pathogens isolated from individual horses with UTI. *P. aeruginosa* can cause lower UTI in some horses, but it can also be isolated from the urethra of many clinically normal horses. Gram-positive organisms are less frequent causes of UTI in horses, although *Staphylococcus* and *Corynebacterium* species are occasionally identified pathogens.[120] In horses with abnormal urine flow (e.g., with uroliths) or instrumentation of the urinary tract (e.g., indwelling bladder catheters, ureteral stents), UTI with *Enterococcus* species (formerly *Streptococcus faecalis*) may also develop. Similarly, lower UTI with *Candida* species develop commonly in recumbent neonatal foals receiving broad-spectrum antibacterial therapy.

34.12.1 Clinical Findings

Clinical signs with UTI usually reflect the location, severity, and duration of the infection. Lower UTI is typically characterized by recognizable disturbances in urine flow but seldom causes signs characteristic of a systemic infection (e.g., fever, weight loss). Dysuria, stranguria, pollakiuria, and incontinence are consistent with lower UTI. Urine scalding of the perineum may develop with chronic UTI in mares (but should not be confused with estrus), and the sheath opening and dorsal aspects of the hindlimbs may be coated with urine crystals or blood in affected stallions and geldings. Gross hematuria may be observed if urinary calculi are present or if bladder or urethral mucosa has been eroded. Hematuria of bladder origin typically produces hematuria throughout urination, but gross discoloration of urine is most obvious at the end of urination. Hematuria caused by renal hemorrhage was a major component of pyelonephritis reported in seven horses.[121] In an occasional horse, gross pyuria may also be observed as passage of mucopurulent debris in otherwise clear urine. Horses with upper UTI are more likely to have signs characteristic of a systemic infection (e.g., fever, weight loss). However, because UTI is typically accompanied by concurrent lower UTI, dysuria may also be present. As an example, recurrent urethral obstruction with small uroliths may be the presenting complaint for chronic upper UTI.

Rectal examination may help confirm a predisposing cause of lower UTI (e.g., enlarged and atonic bladder, cystic calculi, accumulation of sabulous urine sediment, bladder mass). Chronic cystitis also usually leads to bladder wall thickening; however, this change is not easily detected by rectal palpation. Although ureters are usually not found during rectal examination of the normal horse, careful palpation of the dorsolateral aspects of the caudal abdomen (retroperitoneal space) usually reveals enlarged ureters in horses with upper UTI. With pyelonephritis, palpation may further reveal kidneys that are either enlarged or shrunken and misshapen.

34.12.2 Diagnosis

A diagnosis of UTI is based on clinical signs and laboratory analysis of blood and urine samples. With lower UTI, results of a complete blood count (CBC) and serum biochemical profile are usually within reference ranges,

whereas CBC results with upper UTI often support a systemic inflammatory response. With chronic upper UTI, increased total protein and globulin concentrations are often detected, and when the UTI is bilateral, azotemia may also be present. Detection of greater than 20 organisms and more than 10 white blood cells (WBCs) per high-power field on sediment examination of a urine sample collected during midstream voiding or via bladder catheterization is highly supportive of UTI, and growth of 10^4 or more organisms per milliliter of urine confirms the diagnosis.[122,123] When evaluating a horse for possible UTI, urine samples collected should be examined and processed for bacterial culture within 30 minutes after collection, or they should be refrigerated because bacteria can continue to proliferate when urine is stored at room temperature.[122]

Detection of azotemia, low urine specific gravity, and WBC casts in urine sediment are indicative of bilateral upper UTI, especially when accompanied by signs of systemic illness. Ultrasonographic examination of the kidneys is useful for detecting abnormal renal size, shape, or consistency in horses with upper UTI.[121,124–126] Endoscopic examination of the lower urinary tract is another useful tool for evaluating the integrity of urethral and bladder mucosa, detecting small uroliths, and assessing urine flow from each ureteral orifice.[127,128] With long-standing cystitis, especially when bladder paralysis is the underlying cause, ureteral orifices may become dilated (and appear wide open), allowing for vesiculoureteral reflux and development of ascending pyelonephritis. When unilateral pyelonephritis is suspected on the basis of ultrasonographic findings and absence of azotemia, catheterization of each ureter to collect urine samples from each side of the upper urinary tract can be helpful to document unilateral disease. Ureters may be catheterized by passing sterile polyethylene tubing through the biopsy channel of the endoscope during cystoscopy, or this can be accomplished in mares by directing blunt-ended catheters (e.g., 8-Fr polypropylene) through the urethra into each ureteral orifice.[129]

934
935

34.12.3 Treatment

Treatment of UTI consists of proper antimicrobial therapy and correction, if possible, of predisposing anatomic or functional causes. Selection of the appropriate antimicrobial agent is best determined by prior knowledge of the following:

- Susceptibility patterns of the causative agent(s)
- Concentration of the antibiotic in renal tissue and urine
- Activity of the antibiotic at different pH values
- Ease of administration
- Toxicity
- Expense
- Compatibility with other antimicrobial drugs

Recommended antimicrobial agents for treatment of UTI in horses are discussed next. It should be emphasized that in vitro resistance to a particular antibiotic may not preclude successful treatment with the drug, as long as high concentrations are achieved in urine. Similarly, in vitro susceptibility does not always guarantee a successful response to treatment. For example, *Enterococcus* species are routinely found to be susceptible to trimethoprim-sulfa combinations; however, this pathogen is inherently resistant to these combinations in vivo.[130]

34.12.4 TRIMETHOPRIM/SULFONAMIDE COMBINATIONS

Trimethoprim-sulfonamide combinations have been highly successful in treating lower UTIs in some species.[131–133] Although sulfonamides alone can be effective in treating many lower UTIs,[134] addition of trimethoprim improves antibacterial spectrum without a prohibitive increase in expense or toxicity.[135] When selecting a trimethoprim-sulfonamide combination for treatment of horse with a UTI, metabolism of the sulfonamide should be considered. For example, sulfamethoxazole is largely metabolized to inactive products before urinary excretion, whereas sulfadiazine is excreted largely unchanged in urine.[136]

34.12.5 PENICILLIN AND AMPICILLIN

Penicillin, administered parenterally, is effective for treating upper or lower UTIs caused by susceptible *Corynebacterium, Streptococcus,* and some *Staphylococcus* species.[137] Ampicillin has also been used successfully for treatment of both upper and lower UTIs in animals and human patients.[131,138] Although many isolates of the Enterobacteriaceae family demonstrate resistance to ampicillin in vitro, this drug is highly concentrated in urine, and many organisms that are resistant in vitro may be killed in the urine of treated animals.

34.12.6 GENTAMICIN AND AMIKACIN

Gentamicin and amikacin, which can be nephrotoxic, should be reserved for treating lower UTIs caused by highly resistant organisms or acute, life-threatening upper UTIs caused by gram-negative organisms. Pharmacokinetic studies in adults and foals are available.[139,140] Potentiated penicillins (ticarcillin or ticarcillin/clavulanic acid) may be considered as an alternative to aminoglycosides in horses with severely compromised renal function (e.g., creatinine >3.0 mg/dL).

34.12.7 CEPHALOSPORINS, TETRACYCLINES, AND CHLORAMPHENICOL

Cephalosporins, tetracyclines, and chloramphenicol are frequently and effectively used for treatment of UTIs in other species.[138] Cephalosporins are concentrated in urine. Ceftiofur has broad-spectrum antimicrobial activity and could be selected when urinary pathogens demonstrate resistance to trimethoprim-sulfonamide combinations or penicillin. Tetracycline and chloramphenicol are predominantly metabolized in the liver with variable excretion in bile. However, when acceptable serum concentrations are achieved, excretion of active drug into urine may be high enough that either drug may be effective for treatment of UTIs caused by susceptible organisms.[141,142]

34.12.8 OTHER ANTIMICROBIAL AGENTS

Nitrofurantoin has an impressive in vitro spectrum, demonstrating activity against most common gram-negative organisms, including *Salmonella*.[126] The drug is inexpensive, is easily administered as an oral suspension, and achieves high concentrations in urine. Although this antimicrobial agent has not been well studied in horses, adverse effects and acquired resistance appear to be uncommon. However, nitrofurantoin does not attain high concentrations within renal parenchyma; thus, efficacy in treating upper UTI would be questionable. Further limitations of nitrofurantoin usage include decreased antimicrobial activity at an alkaline pH, and increased risk of toxicity has been described in other species as GFR falls (e.g., with CRF). Because urine concentration and

antimicrobial activity of nitrofurantoin after oral administration have not been well substantiated in horses, use of this antibiotic should be reserved for select cases in which specific susceptibility of a gram-negative organism has been demonstrated, or when expense precludes selection of another antibiotic for long-term therapy.

It is not unusual to find highly resistant organisms in urine of horses with chronic UTIs, especially those with bladder paralysis that have been repeatedly catheterized and have received a variety of antibiotic agents. In some cases the organisms may be highly resistant to all drugs approved for use in the equine. I have successfully treated a few adult horses and a yearling with UTI with enrofloxacin (2.5 mg/kg orally [PO] every 12 hours) without apparent adverse effects. Potential cartilage damage in younger horses should be considered and discussed with the owner before treatment with enrofloxacin would be pursued.

When treating UTIs in horses, antimicrobial therapy should be continued for at least 1 week for lower UTIs and for 2 to 6 weeks for upper UTIs. Ideally, a midstream-voided urine sample should be submitted for bacterial culture 2 to 4 days after initiation of therapy and again 1 to 2 weeks after treatment has been discontinued. If the UTI recurs and the same organism is isolated, a focus of upper UTI should be suspected. Ultrasonographic or nuclear scintigraphic examination of the kidneys should be considered in such cases to rule out a nephrolith or other parenchymal disease. Cystoscopy and ureteral catheterization can also be pursued to evaluate for unilateral or bilateral infection of the upper tract. In contrast, recurrence of UTI with a different pathogen suggests an anatomic or functional cause of abnormal urine flow as a predisposing cause of recurrent lower or upper UTI.

34.12.9 URINARY INCONTINENCE

ELIZABETH A. CARR

Urinary incontinence in the horse can result from urolithiasis, congenital anomalies or defects of the lower urinary tract, trauma, neoplasia, neurologic diseases accompanied by bladder dysfunction, and decreased urethral tone. Bladder and urethral calculi frequently result in transient incontinence secondary to cystitis or partial obstruction. Ectopic ureter and other congenital malformations of the urinary tract generally produce incontinence from birth, although development of incontinence in adult horses has been described.[143–146] Traumatically induced incontinence may develop after breeding injury or dystocia in mares or in both genders after sacral or spinal injury.[147] Incontinence has also been speculated to develop with long-standing lumbosacral or lower back problems that make it difficult for horses to posture to urinate. Over time, incomplete bladder emptying allows crystals normally present in equine urine to accumulate in the ventral aspect of the bladder. This crystalloid sediment becomes heavy and in some cases quite firm and further prevents complete bladder emptying. This condition, which has been termed *sabulous urolithiasis,*[148] can accompany bladder paralysis of any cause but may also be able to produce myogenic bladder dysfunction in the absence of an underlying neurologic problem. Horses with neoplasia of the lower urinary tract can also present with incontinence, but other complaints (e.g., stranguria or hematuria) are usually reported as well.

935 936

Neurologic disorders that often result in bladder paralysis and incontinence include equine herpesvirus (EHV) myelitis, cauda equina neuritis, and sorghum toxicosis. These diseases, along with other problems affecting gray matter of the sacral segments (e.g., an occasional horse with equine protozoal myelitis), result in loss of lower motor neuron function, whereas lesions of the lumbar or higher portions of the spinal cord result in loss of upper motor neuron function. Lower motor neuron damage leads to loss of detrusor function and overflow incontinence. A large, easily expressed bladder is found on rectal palpation. Initially, upper motor neuron disease is characterized by increased urethral resistance, leading to increased intravesicular pressure before voiding can occur. Voiding may occur as short bursts of urine passage with incomplete bladder emptying, and rectal examination may reveal a turgid bladder that is small to increased in size. Although upper motor neuron signs

are initially different from those of lower motor neuron disease, incontinence is usually not recognized until overflow incontinence develops as a result of sabulous urolithiasis and progressive loss of detrusor function. The latter progression can explain why bladder paralysis and incontinence may occasionally be found in horses with other neurologic diseases, such as cervical stenotic myelopathy, equine degenerative myelopathy, and even viral encephalomyelitis. Presence of other signs associated with lower motor neuron dysfunction (e.g., loss of anal or tail tone) or upper motor neuron dysfunction (e.g., ataxia) may aid in differentiating the inciting cause of bladder paralysis. Despite many possible causes, the prognosis for recovery from incontinence resulting from bladder paralysis is generally poor because sabulous concretions and UTI quickly complicate the problem.

A final syndrome of incontinence caused by decreased urethral sphincter tone has been reported in a few mares.[149,150] This condition has been attributed to hypoestrogenism because incontinence improved after treatment with exogenous estrogen.

34.12.9.1

Diagnosis

In addition to taking a complete history and performing physical and neurologic examinations, it is helpful to observe the incontinence or any attempts made by the animal to urinate. Rectal palpation, transrectal ultrasonography of the bladder, and endoscopy of the lower urinary tract are useful to rule out uroliths, neoplasia, and congenital anomalies as causes of incontinence. Although most affected horses remain nonazotemic (unless significant obstruction or bilateral pyelonephritis has developed), laboratory analyses of blood and urine, including a quantitative urine culture, should be performed in all horses with incontinence because UTI is a common sequela. Urethral and bladder pressure profiles can be used to assess urinary sphincter and detrusor muscle function. Normal values for both mares and geldings have been reported.[151–153] When an underlying neurologic problem is suspected, cerebrospinal fluid (CSF) collection and analysis may also be of value.

A review of 21 horses presented to Michigan State University's Veterinary Teaching Hospital between 1995 and 2000 with a primary complaint of incontinence revealed that 15 horses had bladder paralysis, three had urolithiasis, and one foal had bilateral ureteral ectopia. Another horse had incontinence of undetermined cause that appeared to respond to treatment with phenylbutazone. The remaining horse had a urachal diverticulum, hydroureters, cystitis, pyelonephritis, an atonic bladder, and urethral sphincter dysfunction that was supported by an abnormal urethral pressure profile. Of the 15 horses with bladder paralysis, four developed the problem after foaling, two of which had dystocia. Fat necrosis around the urethra and bladder neck was found postmortem in one of the latter mares. Bladder paralysis was attributed to equine protozoal myelitis (EPM) in two horses and to EHV myelitis, cauda equina neuritis, and cervical stenotic myelopathy in one horse each. One horse had segmental neuronal degeneration in the lumbosacral and caudal spinal cord, and another horse had histopathologic evidence of denervation atrophy of the detrusor that was attributed to prior spinal cord trauma. An underlying neurologic disease causing bladder paralysis could not be determined in the remaining four horses. Although originally presented for evaluation of acute-onset severe spinal ataxia and weakness, another mare developed signs of an upper motor neuron bladder dysfunction (squirts of urine and a turgid bladder on rectal palpation) during hospitalization. Bladder function returned to normal as the neurologic disease improved over 2 weeks.

34.12.9.2

Treatment

Treatment for incontinence varies with the underlying cause. Removal of calculi and appropriate antimicrobial therapy are effective treatments for urolithiasis. Surgical correction is generally needed for treatment of

congenital anomalies, but owners should be discouraged from using affected animals for breeding. EHV myelitis and EPM carry the most favorable prognoses for recovery, although bladder paresis may persist for several weeks. Removal of sabulous crystalloid material (by bladder lavage through a catheter or by cystotomy) and temporary placement of an indwelling bladder catheter are indicated in cases of recent onset of bladder paresis, to prevent continued distention and further damage to the detrusor. Antimicrobial treatment, ideally based on urine culture results, is also indicated in all horses with bladder paralysis.

Bethanechol (0.25 to 0.75 mg/kg SC or PO every 8 to 12 hours), a parasympathomimetic agent that appears to have a somewhat selective effect on smooth muscle of the GI tract and bladder, has been recommended for improving detrusor tone and strength of contraction in horses with bladder paralysis. However, response to treatment has usually been disappointing, perhaps because of long-standing paralysis before incontinence is recognized. Use of phenoxybenzamine (0.7 mg/kg PO four times daily), an α-adrenergic blocker that decreases urethral sphincter tone, has also been recommended in combination with bethanechol in cases with upper motor neuron bladder dysfunction. In horses with evidence of urethral sphincter hypotonia, the sympathomimetic agent phenylpropanolamine (1 mg/kg PO every 8 to 12 hours) has also been used, but a successful response has not been reported. Dosing regimens for these autonomic drugs have been extrapolated from other species because no pharmacokinetic data are available for the equine species.

936

937

In general, treatment with these autonomic drugs has largely been ineffective in controlling incontinence resulting from bladder paralysis, and the long-term prognosis for recovery is usually poor. On a more positive note, treatment of a few mares with urethral sphincter hypotonia with estradiol cypionate or benzoate (5 to 10 μg/kg intramuscularly [IM] every other day) has been effective at resolving incontinence as long as detrusor function was normal. Estrogen may modulate the effect of norepinephrine on α-receptor activity in the urethral sphincter, thereby improving urethral sphincter tone. Of further interest, incontinence in two mares with partial detrusor dysfunction was also reported to improve after treatment with estrogen,[150] although the mechanism by which estrogen would improve detrusor function is not clear.

34.12.10 ECTOPIC URETER

THOMAS J. DIVERS

Although rare, ectopic ureter is the most frequently reported developmental anomaly of the equine urinary tract. Of the cases reported, almost 90% have been fillies, and the primary complaint is urinary incontinence and perineal dermatitis (urine scalding).[154–157] However, this gender distribution may reflect easier recognition of urinary incontinence in females rather than a true gender predilection. In the male, intermittent urine dripping from the end of the penis is less easily recognized; further, urine entering the pelvic urethra may pass retrograde into the bladder.

34.12.10.1 Diagnosis

Ectopic ureter should be suspected in young horses with incontinence observed shortly after birth. Renal function is usually normal, but the affected ureter may be extremely dilated. In young foals (e.g., <50 to 75 kg) an excretory urogram (after IV administration of contrast agent) or pyelography (after percutaneous injection of contrast agent into renal pelvis via ultrasonographic guidance) may aid in diagnosis of ectopic ureter.[157,158] Unfortunately, most patients are not presented until they are too large for this procedure to be performed (Fig. 34-5). Ultrasonographic examination may reveal mild dilation of the renal pelvis on the affected side. Vaginoscopic and cystoscopic examinations should also be pursued in older foals to determine whether the

problem is unilateral or bilateral, and when unilateral, to determine which ureter is ectopic. In the latter case, cystoscopic examination should reveal urine entering the bladder from only one normal ureteral opening, located at either 2 or 10 o'clock in the bladder neck. Urine can be seen squirting from normal ureteral openings every 20 to 30 seconds. Observation of normal bouts of voiding, in addition to incontinence, further supports a unilateral problem. To determine the location of the opening of the ectopic ureter, visual examination of the vestibule and vagina (using a blade speculum) should be performed initially to look for intermittent urine flow from the area of the urethral papilla. Ectopic ureteral openings are usually not apparent unless urine flow is seen. Intravenous administration of dyes including sodium fluorescein (10 mg/kg IV; yellow-green color), indigotindisulfonate (indigo carmine, 0.25 mg/kg IV; blue-purple color), azosulfamide (2.0 mg/kg IV; red color), or phenolsulfonphthalein (1.0 mg/kg IV; red color) to discolor the urine may aid in location of ectopic ureteral openings.[154,155]

Fig. 34-5 Urine scalding in an 8-month-old thoroughbred filly with a left ectopic ureter. The filly recovered after a nephrectomy.

34.12.10.2 Treatment

If the ectopic ureter is unilateral, creatinine is normal, and ultrasonographic examination of the opposite kidney appears normal, the preferred treatment may be surgical removal of the kidney on the affected side and ligation of the ureter. Nephrectomy may produce an increase in creatinine (0.5 to 1 mg/dL) for a few days, but creatinine returns to the prenephrectomy value within a week. If both ureters are ectopic, which is not unusual, implantation of the distal ureters into the bladder neck should be attempted. Several surgical techniques have been described, but complications can include ascending infection, resulting from dilated ureters, and development of adhesions.[154–157]

34.12.11 NEOPLASIA

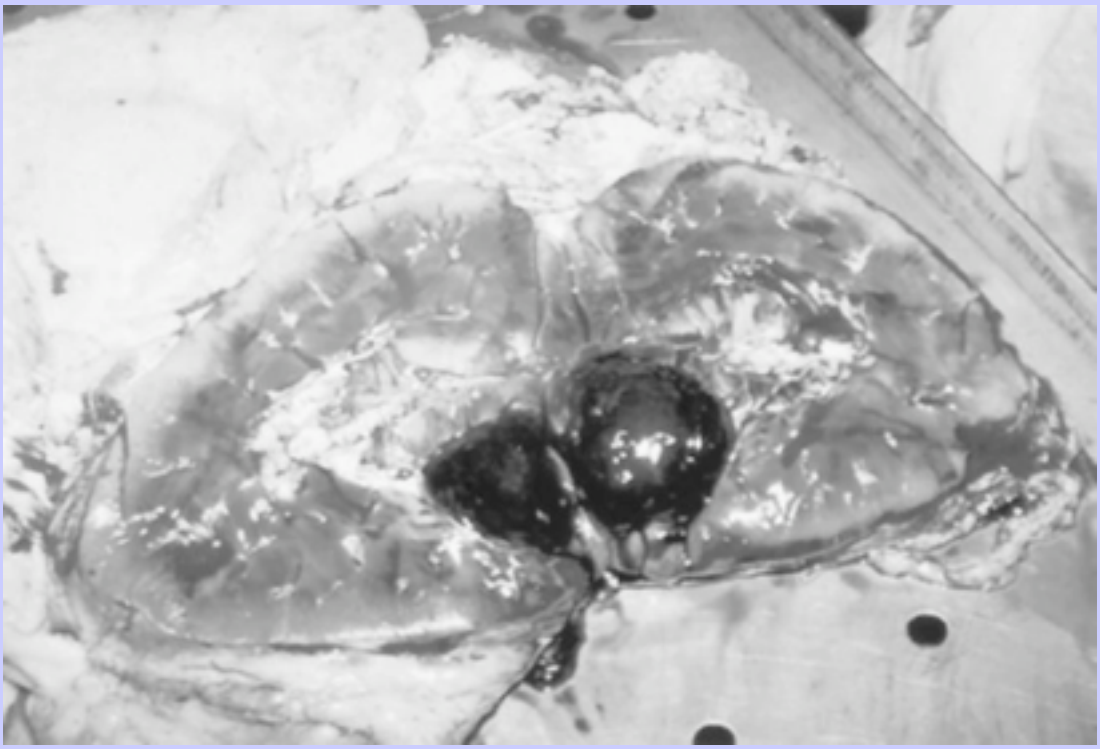
THOMAS J. DIVERS

Neoplasia of the urinary tract is rare in horses. Primary kidney neoplasms include renal cell carcinoma and nephroblastoma, with the former being the most common tumor of the kidney.[159] Renal cell carcinoma (or adenocarcinoma) occurs more frequently in older horses, but nephroblastomas may be detected in young horses. Squamous cell carcinoma is the most common bladder tumor, but horses may also develop transitional cell carcinoma.[160,161] Fibromatous polyps may also occur in younger horses, but bladder tumors usually develop in middle-age to older horses. Adenoma, lymphosarcoma, hemangiosarcoma, and melanoma may also involve the kidneys and, on rare occasions, the bladder.[162,163]

34.12.11.1 Clinical Signs and Diagnosis

Clinical signs in horses with renal neoplasia include hematuria, weight loss, and recurrent colic. Sudden death may occur if the neoplasm hemorrhages into the abdomen or thorax. Renal tumors may result in marked enlargement of the kidneys such that both left and right kidneys may be found on rectal palpation. In other cases, tumors may be small, circumscribed lesions within a kidney (Fig. 34-6) that cannot be felt during rectal palpation. Small tumors may also be difficult to visualize on ultrasonographic examination. The diagnosis is based on history, clinical signs, and ultrasonographic findings (Fig. 34-7). Affected horses usually are not azotemic, but mild anemia may be detected when gross hematuria is observed. Although neoplastic cells are unlikely to be found in urine, cytologic examination of urine sediment is warranted. Nephroblastoma usually remains limited to the kidney, but renal cell carcinomas typically metastasize to the liver and lungs. Thoracic radiographs are helpful in detecting pulmonary metastases. With ultrasonographic guidance, the tumor can usually be biopsied and a definitive diagnosis established.

Fig. 34-6 Cut section of the left kidney from a 25-year-old horse with chronic weight loss, hematuria, and severe anemia. The kidney appeared normal, except for a small, 4 × 5—cm carcinoma with surrounding hemorrhage.



In addition to hematuria and weight loss, horses with bladder tumors may also present with pollakiuria and stranguria. With bladder tumors, a mass can usually be palpated on rectal examination, but it should not be confused with a cystolith or accumulation of sabulous concretions in the ventral aspect of the bladder. Horses with gross hematuria may be mildly anemic but usually are not azotemic. Other than hematuria and associated proteinuria, urinalysis results are often unremarkable; however, with bladder tumors, cytologic examination of urine sediment is more likely to reveal neoplastic cells than with renal tumors.[160,164] A diagnosis of bladder neoplasia may be confirmed by cystoscopic examination and biopsy (Fig. 34-8).

Fig. 34-7 Sonogram of the left kidney area of a 19-year-old horse with chronic hematuria. A 26 × 20 × 19—cm echocavitated mass (renal carcinoma) originates from the left kidney.

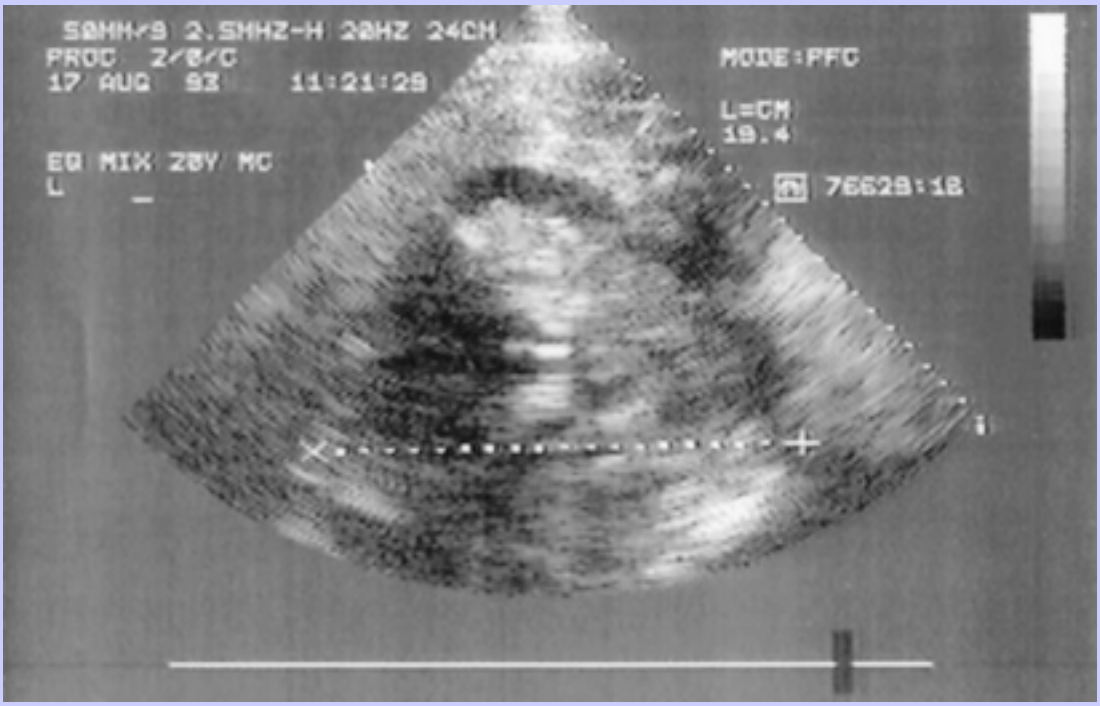


Fig. 34-8 Cystoscopic image of a squamous cell carcinoma of the bladder causing intermittent hematuria in a 14-year-old warmblood mare. The endoscope has been passed beyond the tumor and retroflexed to provide a view directed caudally; a pool of urine is in the foreground, and the tumor can be seen in the ventral aspect of the bladder neck.

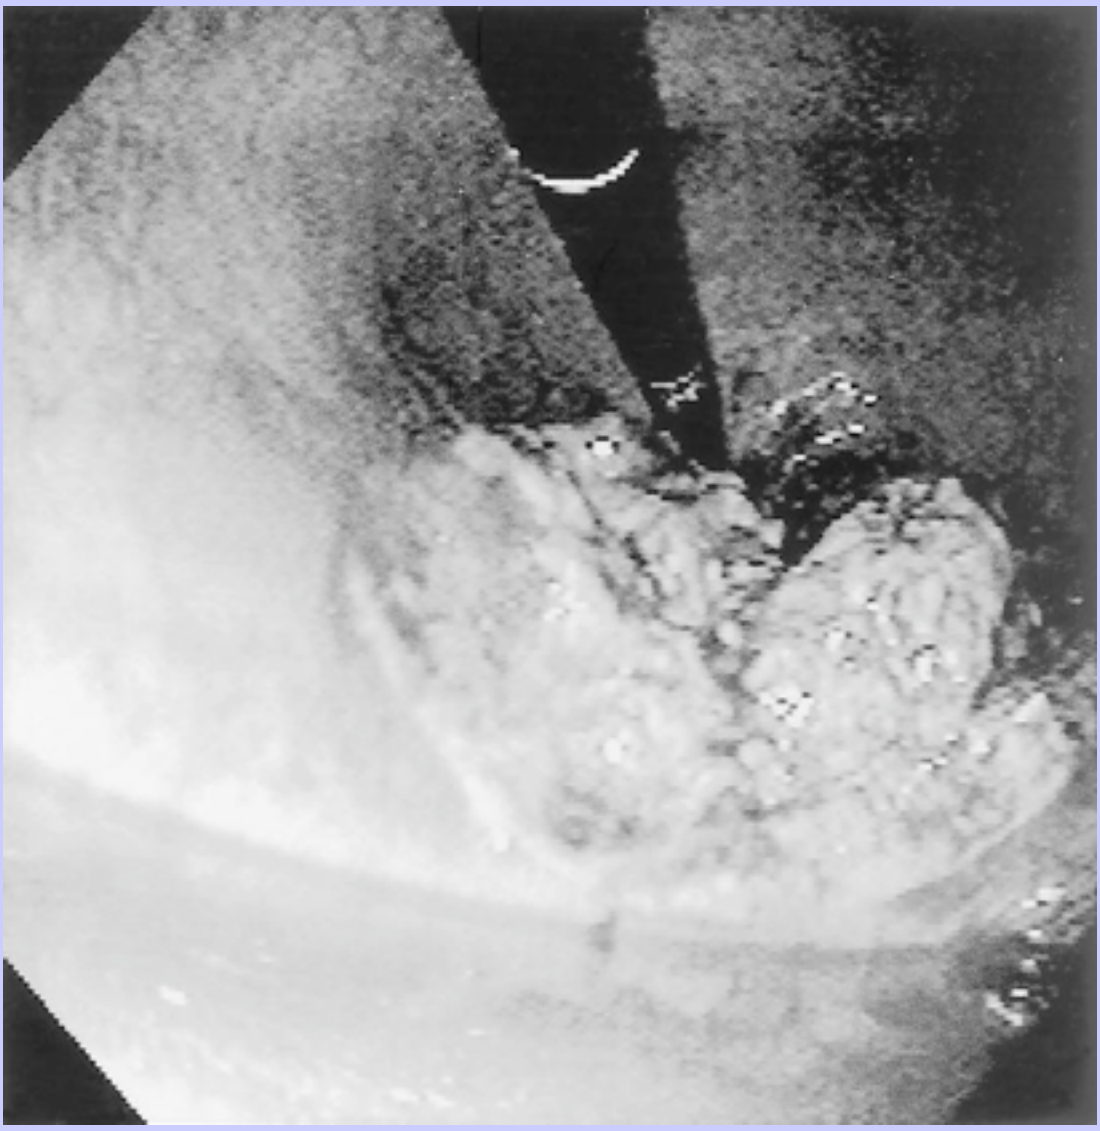


In addition, tumors may metastasize, and the initial signs may be as varied as a lameness[165] or an ulcerated mass on the premaxilla.[166] Tumors can also metastasize to the lung.[167]

Multiple myeloma involving the kidney resulted in hypercalcemia and a high serum parathyroid hormone—related protein concentration.[168] Hypoglycemia was the chief clinical sign in a 6-year-old horse with renal cell carcinoma, which was producing insulin-like growth factors.[169]

34.12.11.2 Treatment

The treatment of choice for unilateral renal neoplasia is nephrectomy. Unfortunately, most cases of renal cell carcinoma have metastasized by the time the diagnosis is made, and surgical intervention is of little benefit to horses with disseminated disease. Thus, careful evaluation for metastatic disease should be pursued before contemplating a nephrectomy. Treatment of bladder tumors includes surgical excision and/or topical chemotherapy using either 5-fluorouracil or triethylenethiophosphoramide.[160]

34.12.12 UROLITHIASIS AND OBSTRUCTIVE DISEASE

THOMAS J. DIVERS

34.12.13 RENAL AND URETERAL CALCULI

Renal and ureteral calculi can produce partial or complete obstruction of one or both sides of the upper urinary tract. Nephroliths usually develop within or adjacent to the renal pelvis, and obstruction can lead to hydronephrosis. Most ureteroliths likely originate as nephroliths that pass into the ureter, where they become lodged and enlarge over time. Ureteral stones have a propensity to lodge in the distal ureter and can sometimes be palpated rectally dorsal and lateral to the bladder neck. Occasionally, small nephroliths may pass all the way down the ureter into the bladder; unlike their human counterparts, affected equine patients are rarely recognized to manifest renal colic.[170,171] Renal and ureteral calculi are most often composed of calcium carbonate crystals; calcium phosphate stones may occasionally develop. Although usually not recognized clinically, a nidus of damaged tissue (e.g., interstitial inflammation, infection, or fibrosis; area of medullary crest necrosis adjacent to renal pelvis) is likely necessary for initiation of stone formation. Anomalies of development (e.g., renal hypoplasia, dysplasia, polycystic disease) or prior exposure to nephrotoxins could also provide a nidus for stone formation.

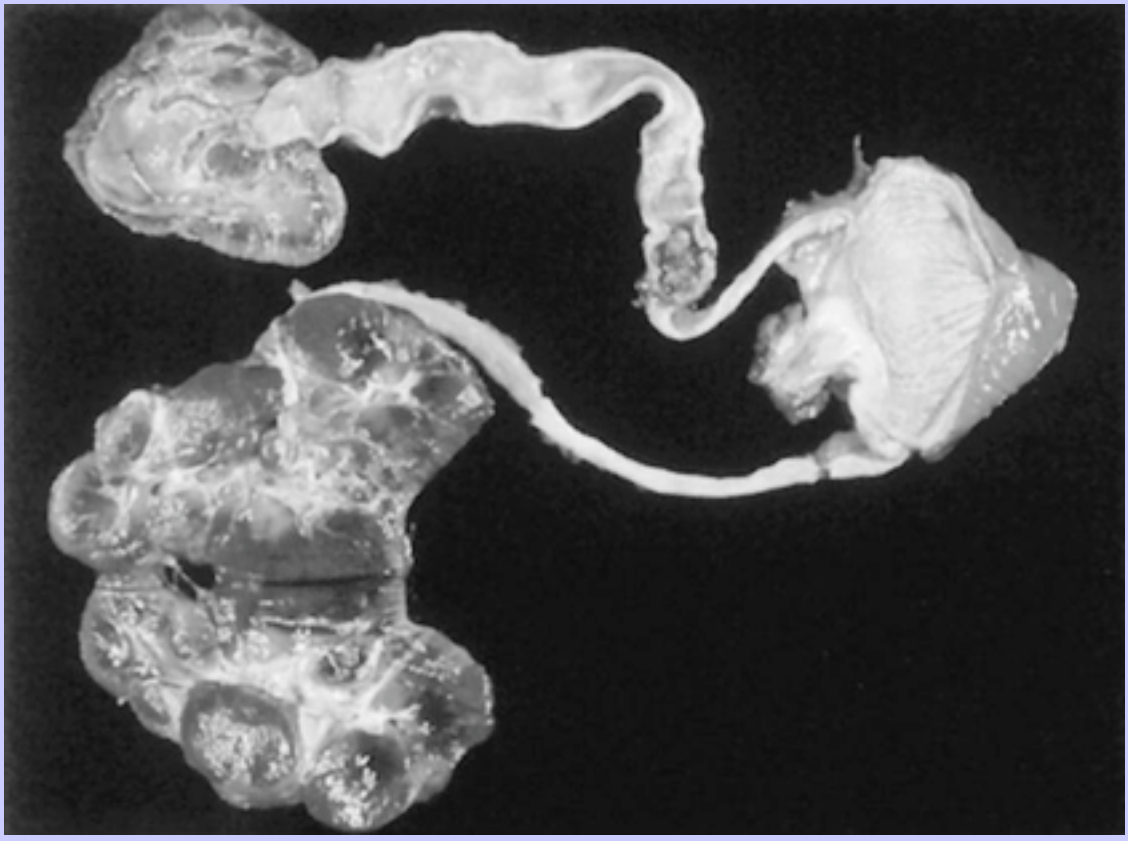
938

939

Bilateral nephrolithiasis and ureterolithiasis has been best described in a series of young adult racehorses, and development of subclinical medullary crest necrosis as a result of NSAID use was a suggested risk factor[172]; this was also seen in a 2-year-old gelding.[173] When both sides of the upper tract are affected, the condition typically progresses to CRF before horses are presented for evaluation (Fig. 34-9). As described for CRF, the most common presenting complaint is weight loss, but polyuria and poor performance may be earlier complaints in competitive horses. Establishing a diagnosis of urolithiasis causing unilateral upper tract obstruction is more challenging because clinical signs are mild (recurrent colic) or nonexistent and azotemia is usually absent. In fact, unilateral upper tract stones may be detected as incidental necropsy findings in horses of all ages. In horses with clinical signs, careful rectal palpation may reveal a turgid ureter and presence of a ureterolith. When passed from the upper tract into the bladder, small uroliths may be voided without problem or may cause urethral obstruction in males. Horses with repeated bouts of urethral obstruction should be thoroughly evaluated for presence of upper tract disease.

In horses with bilateral disease leading to CRF, azotemia and isosthenuria are present. As already mentioned, azotemia is usually absent with unilateral obstruction. With either scenario, gross hematuria is uncommon unless stones have been passed into the bladder or urethra, but urinalysis usually reveals pigmenturia, and microscopic hematuria is confirmed by examination of urine sediment. Although UTI usually is not present with upper tract obstruction consequent to lithiasis at the initial evaluation, it may develop with catheterization or other instrumentation used for relief of the obstruction. Thus a quantitative urine culture should be considered part of the minimum database, especially if pyuria or bacteriuria is detected on sediment examination. Transabdominal ultrasonography is a valuable tool for detection of nephroliths, dilation of the renal pelvis (or complete hydronephrosis), and fibrosis (increased echogenicity) within the kidney.[174–176] However, small nephroliths (<1 cm in diameter) occasionally can be missed despite a complete ultrasonographic examination. Transrectal ultrasonography is also useful for detection of ureteral dilation and lithiasis.

Fig. 34-9 Urinary tract removed from a 5-year-old standardbred with chronic renal failure caused by intermittent or persistent obstruction by renal and ureteral stones. Note the location of the ureteral obstruction near the bladder. This is the most common site for the obstruction to occur.



If upper urinary tract obstruction is diagnosed before development of more severe azotemia (creatinine >5.0 mg/dL), surgical removal is recommended. A nephrotomy and/or ureterotomy may be required.[170,172] When equipment is available, electrohydraulic lithotripsy is the preferred technique for removal of ureteral stones.[177] This procedure involves passing an endoscope into the ureter until the stone can be seen, then advancing a lithotriptor through the biopsy channel of the endoscope until the end touches the ureterolith (Fig. 34-10, *A*). An irrigating solution is pumped through the endoscope to distend the distal ureter, and an electrical impulse delivered by the lithotriptor causes a shock wave at the surface of the stone. Because the majority of calcium carbonate stones are inherently fragile,[178] fragmentation by lithotripsy is usually rapid (Fig. 34-10, *B*), and remaining fragments are flushed distally by further infusion of irrigating solution (Fig. 34-10, *C*). Before surgical intervention is pursued, both kidneys should be thoroughly evaluated for evidence of other stones because upper tract lithiasis is often bilateral.

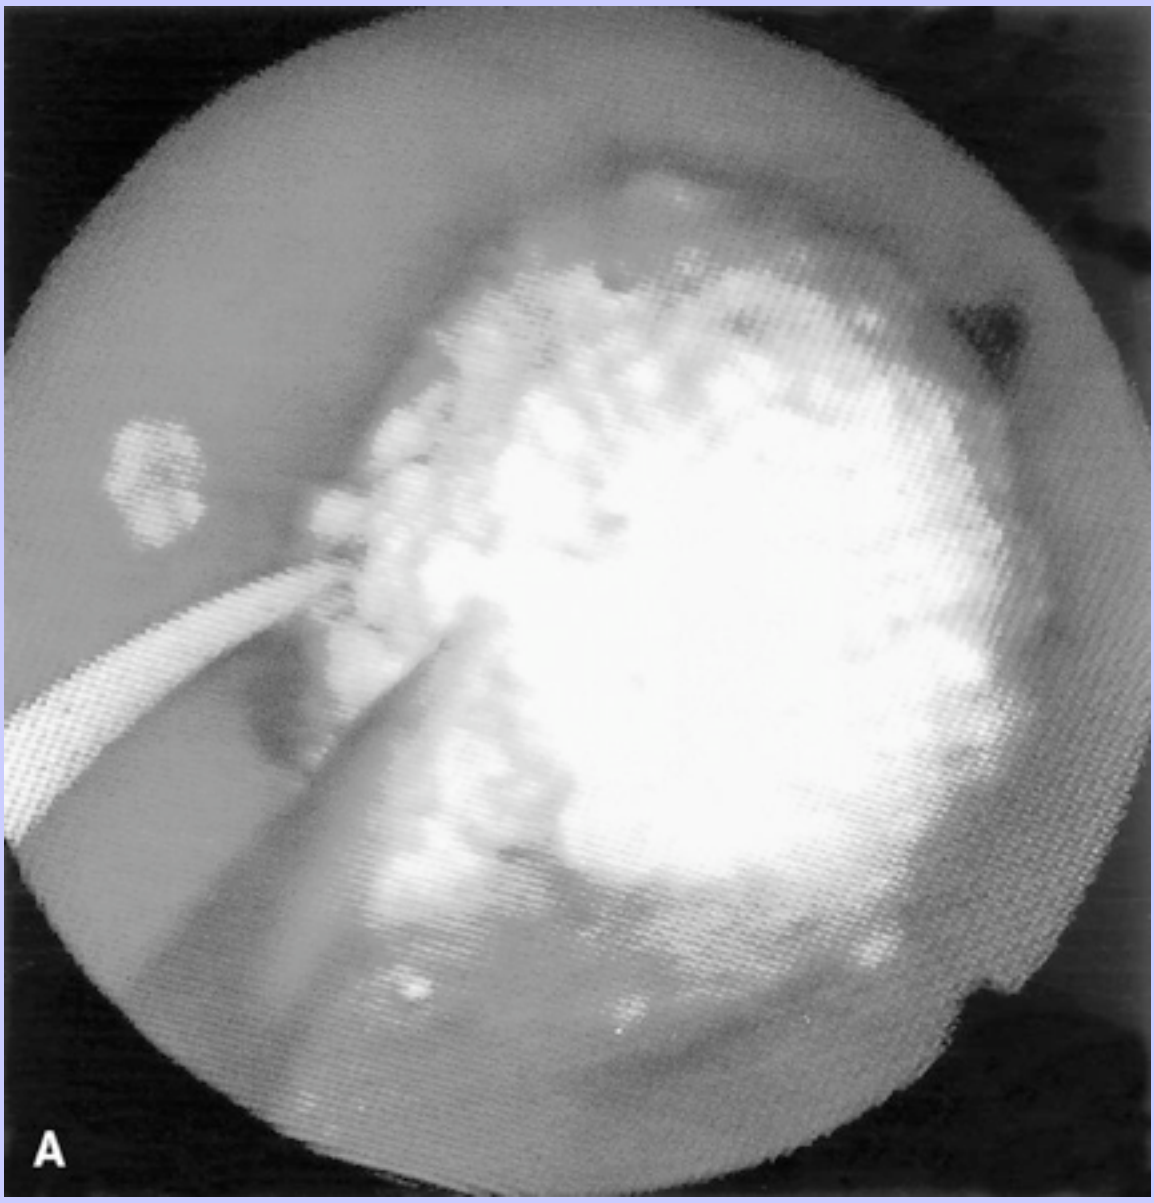
In addition to intermittent signs of mild colic, unilateral nephroliths may occasionally cause intermittent or persistent gross hematuria. In the absence of azotemia and evidence of disease of the contralateral kidney, unilateral nephrectomy is the treatment of choice for obstructing nephroliths and remains a reasonable alternative to lithotripsy for treatment of unilateral ureteroliths[179] (Figs. 34-11 and 34-12).

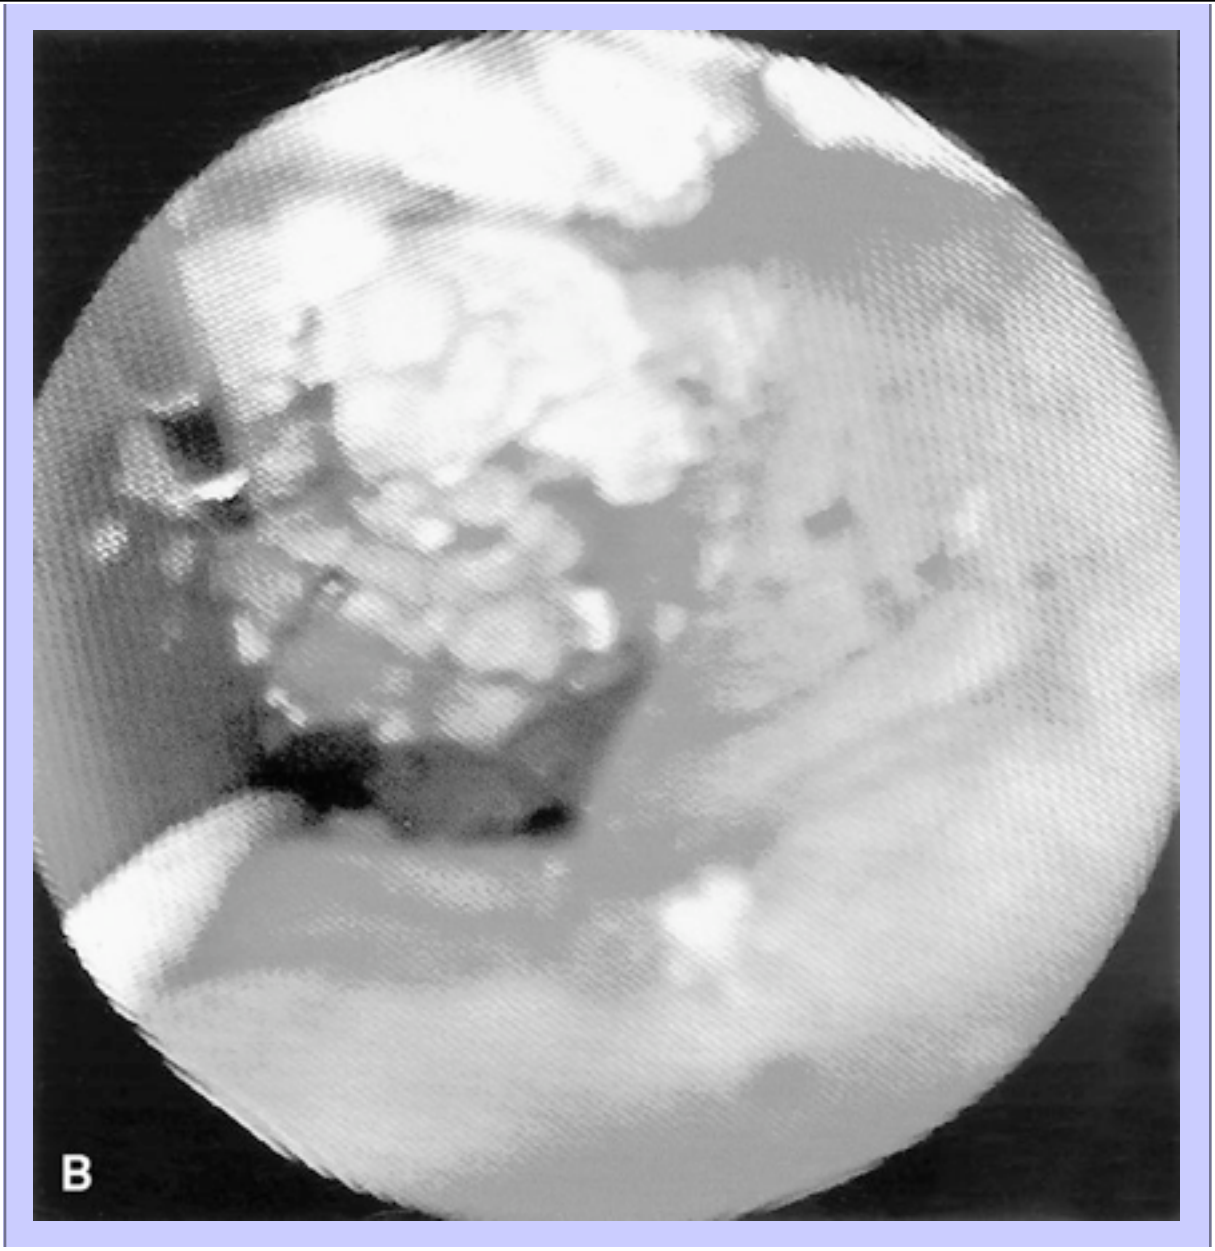
34.13 CYSTIC CALCULI

Although occurrence is rare compared with other species, cystolithiasis is the most common form of urolithiasis in horses, and intact males appear to be at greater risk.[171,180] Calculi that develop in the bladder are usually single, large spiculated stones composed of calcium carbonate crystals.[178,180,181] Less often, stones are a mix of calcium carbonate and calcium phosphate crystals; these stones often have a smooth surface and are more resistant to fragmentation.[182] Risk factors for development of bladder stones in horses are not well understood, but anatomic defects (e.g., diverticuli) or suture material persisting from prior bladder surgery may predispose horses to cystic calculi. Although bacteria can often be detected by culture of the center of equine calculi, their role in stone formation is unclear.[171] Considering that normal equine urine is rich in calcium carbonate crystals, it is surprising that cystoliths are not more common in horses than in ruminants or small animals. Their low occurrence can likely be attributed to the large amount of mucus that is also present in horse urine. Mucus, produced by glands in the renal pelvis and proximal ureter, appears to act as a lubricant to prevent adherence of crystals to uroepithelium.

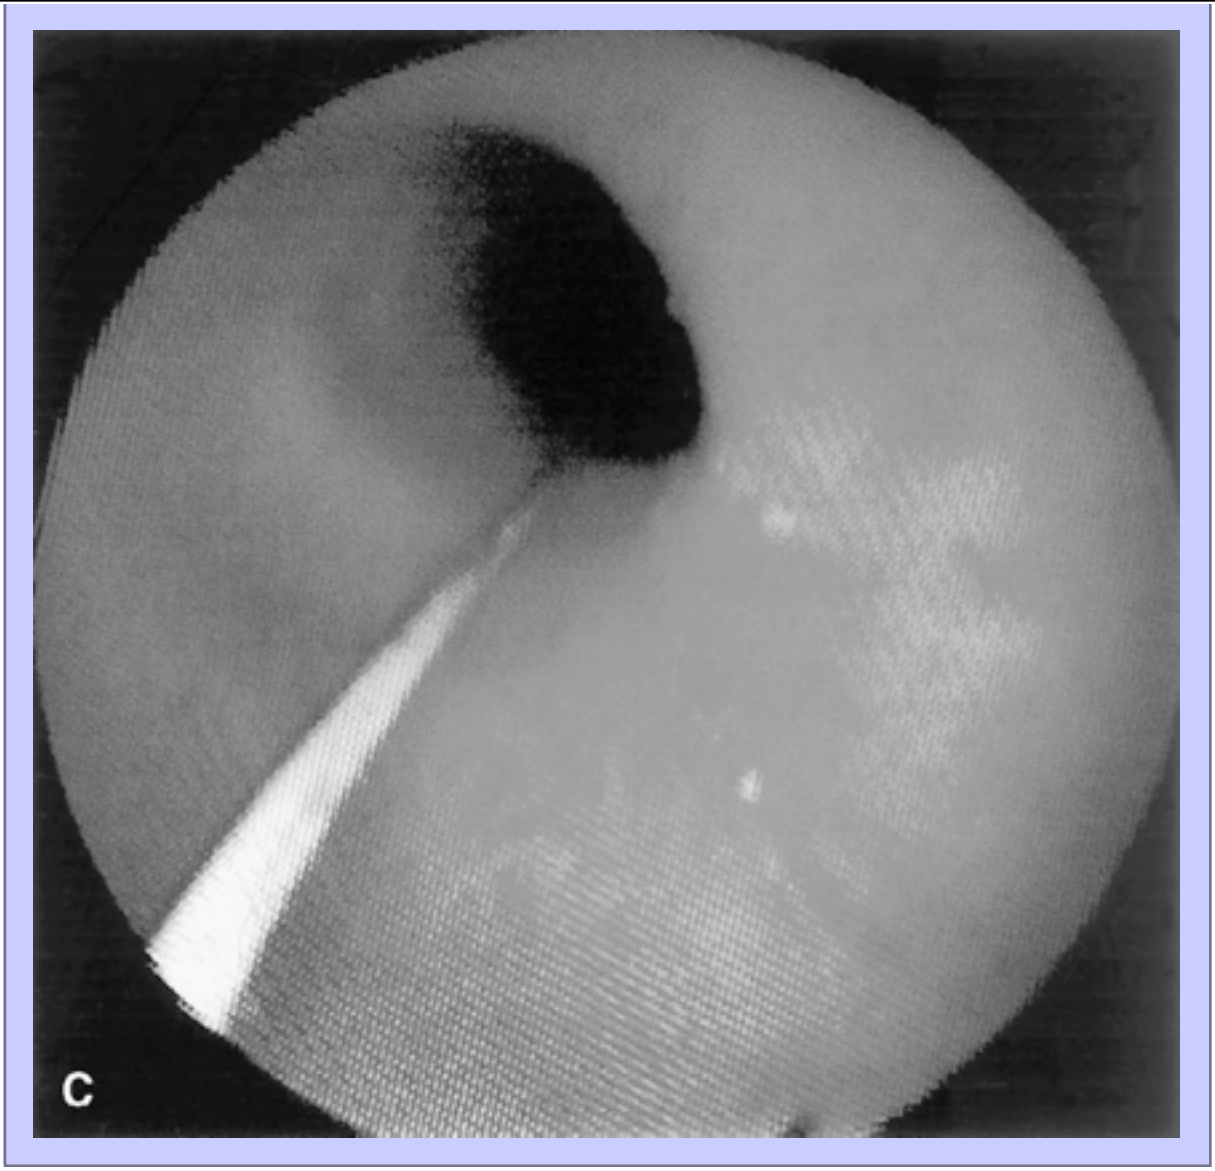
The most common clinical sign exhibited by horses with cystic calculi is hematuria after exercise. Pollakiuria, stranguria, or incontinence may also be observed. Less frequently, dysuria may be caused by accumulation of urine sediment in the ventral aspect of the bladder. This condition, sabulous urolithiasis, usually develops as a result of bladder paralysis.[183] Urinary incontinence is usually present in horses with sabulous urolithiasis, and prognosis is guarded to poor because of underlying detrusor dysfunction.

Fig. 34-10 Endoscopic images of a ureterolith completely obstructing the left ureter. **A**, Immediately before electrohydraulic lithotripsy. **B**, After partial fragmentation. **C**, After complete removal. White instrument is a ureteral stent placed to facilitate passage of the ureteroscope, and gray instrument (in **A** and **B**) is the lithotriptor touching the surface of the ureterolith.





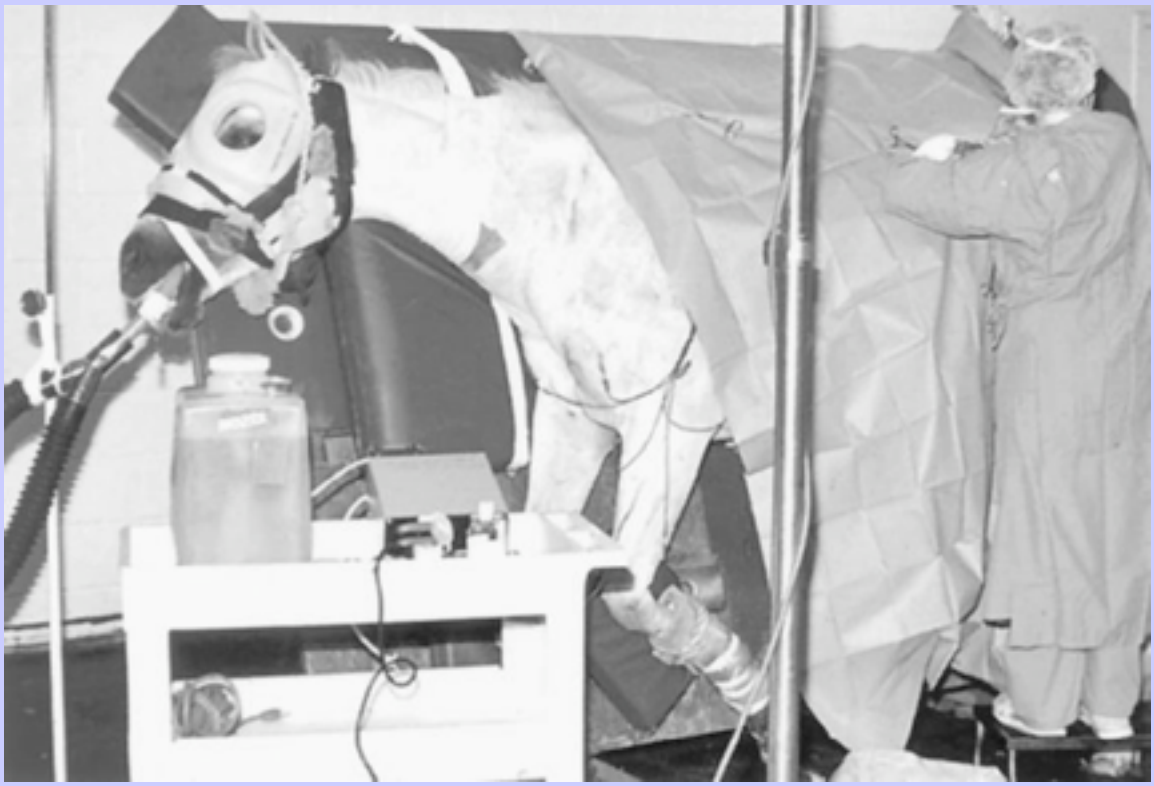
B



Presence of a cystolith can be confirmed by rectal examination. It is important to remember that most bladder stones can be palpated with only the hand and wrist in the rectum. As a result of frequent urination, the bladder is usually small, and cystic calculi can be missed if the examiner passes quickly beyond the calculus during the rectal examination. Careful palpation may also allow discrimination between soft-tissue masses of the bladder (neoplasia) and sabulous urolithiasis. With the latter, firm sediment is usually palpated well over the pelvic brim in the ventral aspect of a distended bladder. Manipulation of the bladder is accompanied by incontinence, and sabulous uroliths may be indentable when palpated after the bladder has been emptied via catheterization. Although rarely needed to confirm the diagnosis, ultrasonographic examination of the entire urinary tract should be considered because calculi may be present in multiple locations. Because UTI can sometimes accompany cystolithiasis, urinalysis and a quantitative urine culture are warranted during the initial evaluation of all horses with bladder stones.

Fig. 34-11 Left kidney of a 12-year-old thoroughbred that presented with a complaint of intermittent hematuria. Right kidney appeared normal on ultrasound examination, and renal function was normal.

Fig. 34-12 Left kidney shown in Fig. 34-11 was removed with the horse anesthetized but strapped to the surgery table in an upright position. This is the preferred surgical position for nephrectomy or nephrotomy in adult horses.



Treatment of cystic calculi usually consists of surgical removal accompanied by a 7- to 10-day course of postoperative antibiotic treatment. Cystotomy can be performed via celiotomy or a pararectal approach (Gäkel's operation) or the stone can be removed after fragmentation with a lithotriptor passed via a perineal urethrotomy.[182,184,185] In mares, urethral sphincterotomy after epidural anesthesia with xylazine has been advocated as a practical method for stone removal. However, with sedation and epidural anesthesia, manual distention of the urethra often allows several fingers or a small hand to be passed into a mare's bladder, and depending on size, the stone can be retrieved intact or after fragmentation. Placing the cystolith into a sterile rectal sleeve or surrounding it with a similar smooth plastic material allows easier removal of spiculated stones and fragments. If available, electrohydraulic or pulsed-dye-laser lithotripsy may be the least traumatic method of fragmentation and removal of bladder stones in both genders; however, success may be limited by the ability to lavage all stone fragments from the bladder.[186–190]

Historically, risk of recurrence after surgery has been considered low; however, in a series of 68 cases of urolithiasis (at all levels of urinary tract), 12/29 horses (41%) with follow-up had recurrence 1 to 32 months after surgery. Recurrence was more common with perineal urethrotomy than cystotomy and was attributed to the former's inability to remove all fragments completely by lavage.[171] This relatively high recurrence rate indicates

that postoperative management changes are warranted to decrease risk of future stone formation. Changing from a legume to a grass hay is the most practical recommendation to decrease urinary calcium excretion. Urinary acidification with ammonium chloride (50 to 200 mg/kg/day PO) or ammonium sulfate (200 to 300 mg/kg/day PO) has also been recommended to decrease the amount of urine crystals in equine urine.[190,191] Unfortunately, these ammonium salts are rather unpalatable and should be administered as two or three doses daily for effective urinary acidification. Further, the actual benefit of urinary acidification in horses has never been established, and recurrence may be more likely related to inadequate mucus secretion or persistence of damaged uroepithelium in the upper or lower tract. A more practical recommendation may be to administer 2 to 4 oz of salt in the feed daily to increase water consumption and urine flow. The increase in urine flow is accompanied by a decrease in urine pH to near-neutral values.

34.14 URETHRAL OBSTRUCTION

Calculi, neoplasms, congenital anomalies, and preputial edema and inflammation may all produce partial or complete obstruction of the urethra. Urethral calculi are most often calcium carbonate stones that lodge in the pelvic urethra in stallions or geldings,[192] and the most common neoplasm causing urethral obstruction is squamous cell carcinoma of the penis.[193] Preputial edema and inflammation may develop as a consequence of trauma or parasitism (habronemiasis). In addition, overweight horses may develop recurrent preputial inflammation and infection associated with fat deposition in the sheath. Horses with the latter condition may fail to drop the penis during urination, and urine scalding within the sheath is likely a contributing factor to recurrent inflammation.

Complete urethral obstruction usually causes moderate to severe signs of colic, and an enlarged, turgid bladder is detected on rectal palpation. Careful palpation of the urethra below the anus may reveal the location of an obstructing urolith or frequent contraction of the urethralis muscle. Rarely, postrenal ARF may develop, or the bladder may rupture. Partial urethral obstruction is usually accompanied by dysuria, incontinence, and urine scalding of the hindlimbs. A diagnosis of urethral obstruction is based on clinical signs, rectal examination findings, external examination of the penis and prepuce, and passage of a catheter or endoscope through the urethra to the bladder.

Treatment of urethral obstruction usually involves surgery. Urethral calculi can be removed either by a subischial urethrotomy over the site of obstruction or by hydropulsion through the urethrotomy incision. Excessive tissue trauma should be avoided because it may increase the risk of urethral stricture and recurrent urolithiasis. Laboratory assessment of fluid and electrolyte status is important for correction of dehydration, azotemia, and electrolyte alterations that may develop with sweating (caused by pain), bladder rupture, or anuria. With squamous cell carcinoma, aggressive surgical resection of involved tissues is warranted with larger lesions, whereas smaller lesions may be amenable to treatment with 5-fluorouracil ointment. However, because recurrence rate of squamous cell carcinoma of the penis and prepuce is 20% or greater,[193] surgical removal should be initially considered in all affected horses. Detrusor function may be decreased if bladder distention had been ongoing for several days, and an indwelling bladder catheter (closed system) or treatment with bethanechol (0.25 to 0.75 mg/kg SC or PO every 8 to 12 hours) may help with recovery of detrusor function.

34.15 IDIOPATHIC RENAL HEMATURIA

HAROLD C. SCHOTT II

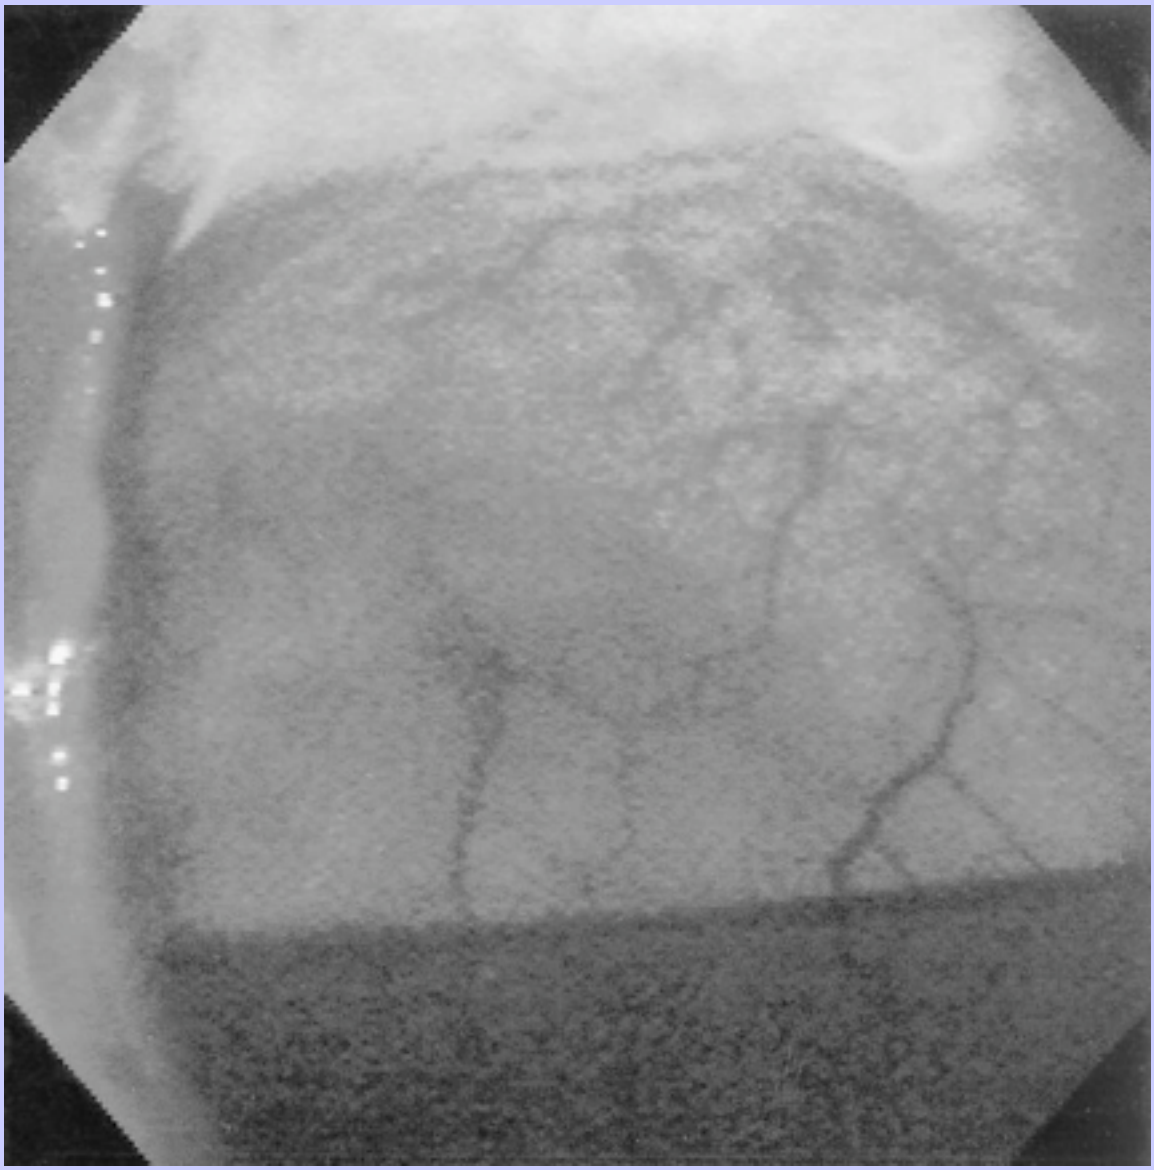
Idiopathic renal hematuria (IRH) is syndrome characterized by sudden onset of gross, often life-threatening hematuria.[194] Hemorrhage arises from one or both kidneys and is manifested by passage of large blood clots in

urine. Endoscopic examination of the urethra and bladder usually reveals no abnormalities of these structures, but blood clots may be seen exiting one or both ureteral orifices. Although a definitive cause of renal hemorrhage may be established in some horses (e.g., renal adenocarcinoma, arteriovenous or arterioureteral fistula),[195,196] the disorder is termed *idiopathic* when a primary disease process cannot be found. Both genders, a wide age range, and several breeds of horses (including a mammoth donkey and a mule) have been affected. However, more than 50% of animals with IRH have been Arabians.

Use of the term *idiopathic renal hematuria* to describe this syndrome of horses was adopted from its use in human patients and dogs with severe renal hemorrhage.[197–201] *Benign essential hematuria* and *benign primary hematuria* are other terms that have been used to describe less severe hematuria that is not associated with trauma or other obvious causes of hematuria. In humans and dogs, hematuria is more often a unilateral than a bilateral problem, similar to what has been observed in the few affected horses. The pathophysiology remains poorly understood, but macroscopic hematuria has been associated with immune-mediated glomerular damage (e.g., acute postinfectious glomerulonephritis, membranoproliferative glomerulonephritis, IgA nephropathy or Berger's disease), thin basement membrane nephropathy, and the loin pain—hematuria syndrome in human patients.

Although hematuria and pigmenturia can accompany several systemic diseases in horses,[202–205] patients affected with IRH appear to have spontaneous, severe hematuria in the absence of other signs of disease. Although one report suggested that severe renal hemorrhage was caused by pyelonephritis,[206] supportive data were lacking. In cases that I managed, neither UTI nor lithiasis has been detected, and the magnitude of hematuria often resulted in the need for repeated blood transfusions. As with hemorrhage associated with guttural pouch mycosis, the syndrome may produce episodic hemorrhage. Initially, hemorrhage is noted by finding a large amount of clotted blood in stall bedding or in the pasture. However, other client complaints (e.g., depression, anorexia, weight loss) are typically absent. Examination may reveal dried blood at the end of the penis or in the sheath of males or on the vulvar lips and between the hindlimbs of mares. In both genders, neoplasia of the external genitalia or urinary tract is an important differential diagnosis, and in mares, varicosities in the area of the vestibulovaginal sphincter also must be considered, especially in multiparous mares. When blood is not detected in the sheath or vulvar areas, further evaluation may be unrewarding because the renal bleeding may cease spontaneously. Bleeding has anecdotally been attributed to cystitis and pyelonephritis, in the absence of positive urine culture results, because hemorrhage stops during a course of antimicrobial therapy. More likely, spontaneous resolution has occurred. Further, the magnitude of hematuria is considerably greater with IRH than with most UTIs; pyuria is absent; and urine culture results are negative. In my experience, one or two initial episodes of hemorrhage are followed by a more severe hemorrhagic crisis within months to 2 years after observation of the initial bleeding episode. Of interest, renal colic has been notably absent in the history of affected horses.

Fig. 34-13 Cystoscopic image of a 19-year-old Arabian mare with idiopathic renal hematuria. A large blood clot can be seen exiting the left ureter, whereas the right ureteral opening appears normal.



34.15.1 Diagnosis

A diagnosis of IRH is made by exclusion of systemic disease, other causes of hematuria, and alterations in hemostasis. Physical examination may reveal tachycardia, tachypnea, and pale membranes consistent with acute blood loss. Rectal palpation may reveal an enlarged, irregular bladder resulting from the presence of blood clots. Azotemia is uncommon. Endoscopic examination is important to document that hematuria is originating from

the upper urinary tract and to determine whether hemorrhage is unilateral or bilateral (Fig. 34-13). Repeated examinations may be required to answer the latter question. Ultrasonographic imaging is necessary to rule out nephrolithiasis or ureterolithiasis and may occasionally reveal a distended vascular space or renal vascular anomaly as the cause of hematuria. Renal scintigraphy can be a useful technique in affected horses, providing semiquantitative information about renal function when a nephrectomy is being considered. Renal biopsy and IF staining may assist in documenting immune-mediated glomerular injury, but the significance of such results is not well understood at this time.

34.15.2 Treatment

Treatment for IRH consists of supportive care for acute blood loss, including blood transfusions. Medications intended to promote hemostasis (e.g., α-aminocaproic acid, formalin) have also been administered, but their efficacy has not been validated. Because the condition may be self-limiting in some patients, supportive care is warranted. With severe and recurrent hematuria of unilateral renal origin, a nephrectomy may be indicated, but owners should be warned that there is a risk of hematuria developing in the contralateral kidney. In my experience, risk of contralateral renal bleeding appears to be greater in the Arabian breed.

34.16 URETHRAL HEMORRHAGE

HAROLD C. SCHOTT II

942

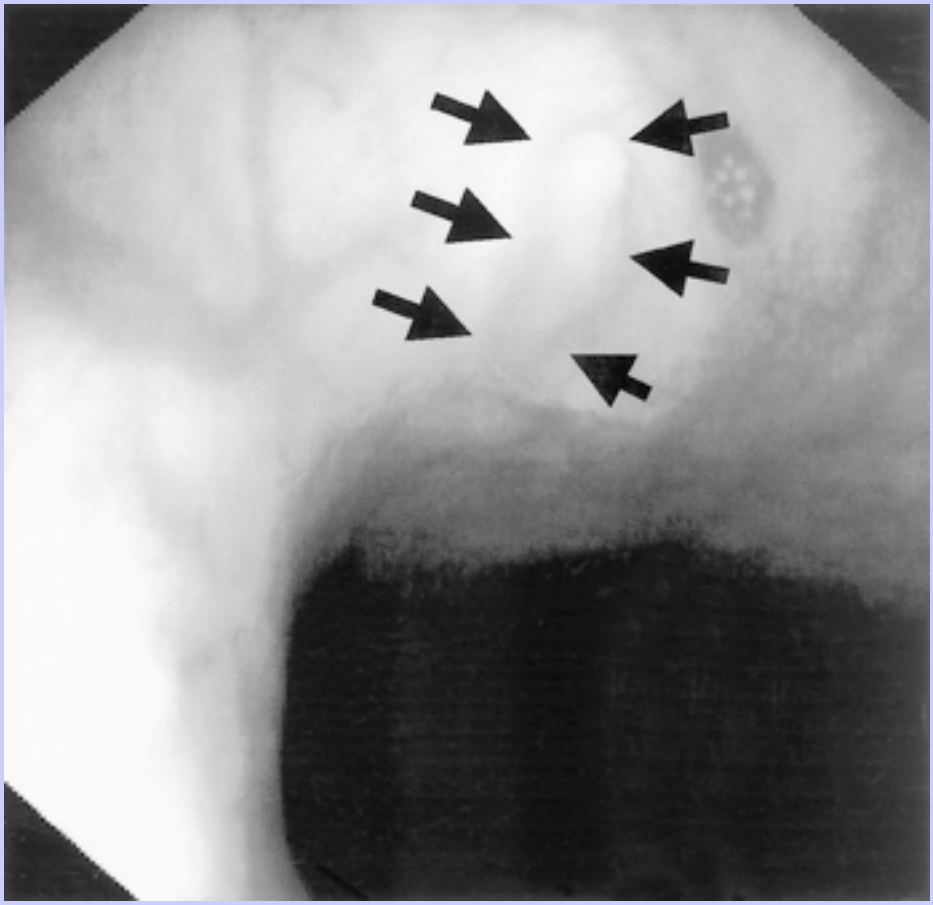
943

Although a recognized cause of hemospermia in stallions, defects or tears of the proximal urethra at the level of the ischial arch are a more recently described cause of hematuria in geldings.[207–209] Urethral defects typically result in hematuria at the end of urination, in association with urethral contraction. Affected horses generally void a normal volume of urine that is not discolored. At the end of urination, a series of urethral contractions results in squirts of bright-red blood. Occasionally, a smaller amount of darker blood may be passed at the start of urination. In most cases the condition does not appear painful or result in pollakiuria. Interestingly, the majority of affected stallions with hemospermia and geldings with hematuria have been quarter horses or quarter horse cross-breeds that have been free of other complaints.[210,211] Treatment with antibiotics for a suspected cystitis or urethritis has routinely been unsuccessful, although hematuria appears to resolve spontaneously in about 50% affected horses. Because the defects are difficult to detect without use of high-resolution videoendoscopic equipment, previous reports of urethral bleeding have been attributed to urethritis or hemorrhage from “varicosities” of the urethral vasculature. However, vasculature underlying the urethral mucosa becomes quite prominent when the urethra is distended with air during endoscopic examination, especially in the proximal urethra (to the point that blood can be seen flowing in the submucosal vasculature). Thus it would be logical to suspect that hemorrhage could arise from an apparent urethritis or urethral varicosity, although these problems are poorly documented in horses.

Examination of affected horses is often unremarkable, and laboratory analysis of blood reveals normal renal function, although mild anemia can be an occasional finding. Urine samples collected midstream or by bladder catheterization appear grossly normal. Urinalysis may have normal results, or an increased number of red blood cells (RBCs) may be found on sediment examination, a finding that would also result in a positive reagent strip result for blood. Bacterial culture of urine yields negative results. The diagnosis is made with endoscopic examination of the urethra, during which a lesion is typically seen along the dorsocaudal aspect of the urethra at the level of the ischial arch. External palpation of the urethra in this area is usually unremarkable but can assist in localizing the lesion because external digital palpation can be seen through the endoscope. With hematuria of several weeks' duration, there is little evidence of inflammation; rather, the lesion appears as a fistula communicating with the vasculature of the corpus spongiosum penis (Fig. 34-14).

Although the pathophysiology of this condition remains unclear, it has been speculated that the defect is the result of a "blowout" of the corpus spongiosum penis (cavernous vascular tissue surrounding the urethra) into the urethral lumen.[209] Contraction of the bulbospongiosus muscle during ejaculation causes a dramatic increase in pressure in the corpus spongiosum penis, which is essentially a closed vascular space during ejaculation. The bulbospongiosus muscle also undergoes a series of contractions to empty the urethra of urine at the end of urination; thus the defect into the urethra may develop by a similar mechanism in geldings. Once the lesion has been created, it is maintained by bleeding at the end of each urination, and the surrounding mucosa heals by formation of a fistula into the vascular tissue. An explanation for the consistent location along the dorsocaudal aspect of the urethra at the level of the ischial arch has not been documented but may be related to the anatomy of the musculature supporting the base of the penis and an enlargement of the corpus spongiosum penis in this area. Further, a narrowing of the lumen at the distal extent of the ampullar portion of the urethra may also contribute to the location of the defects. An anatomic predisposition in quarter horses has not been documented but could be speculated based on an apparent increased risk in this breed.

Fig. 34-14 Endoscopic image of the proximal urethra of a gelding with hematuria at the end of urination. A urethral defect can be seen *between the arrows* along the caudal aspect of the urethra as it passes dorsocranially over the pelvic brim.



Because hematuria may resolve spontaneously, no treatment may be initially required. If hematuria persists for more than a month or if significant anemia develops, a temporary subischial "incomplete" urethrotomy has been successful in some affected geldings. After sedation and epidural or local anesthesia, a catheter is placed in the urethra and a vertical incision made into the corpus spongiosum penis but not into the urethral lumen. The surgical wound requires several weeks to heal, and moderate hemorrhage from the corpus spongiosum penis is apparent for the first few days after surgery. Hematuria should resolve within a week after this procedure. Additional treatment consists of local wound care and prophylactic antibiotic treatment (typically a trimethoprim-sulfonamide combination) for 7 to 10 days.

34.17 POLYURIA AND POLYDIPSIA

HAROLD C. SCHOTT II

Polyuria and polydipsia (PU/PD) are defined as urine output in excess of 50 mL/kg/day and fluid intake of more than 100 mL/kg/day.[212,213] These values equate to production of 25 L of urine and consumption of 50 L of water for a 500-kg horse. It is important to remember that urine production and water consumption vary with age, diet, workload, environmental temperature, and GI water absorption.[214,215] For example, urine production increases by 50% to 100% when the diet is changed from a grass to a legume hay.[216] Similarly, horses in heavy exercise, stabled in hot climates, or with chronic diarrhea may have a water intake in excess of 100 L/day yet produce normal volumes of urine. The major causes of PU/PD in horses include renal failure (discussed previously), pituitary adenoma (Cushing's disease), and primary or "psychogenic" polydipsia. Less common causes include excessive salt consumption, central and nephrogenic diabetes insipidus, diabetes mellitus, sepsis/endotoxemia, and iatrogenic causes (e.g., sedation with α_2-agonists, corticosteroid therapy, diuretic use).[213]

943 944

34.18 POLYURIA/POLYDIPSIA WITH CUSHING'S DISEASE

Pituitary adenoma and the resulting syndrome of hyperadrenocorticism (Cushing's disease) is common in older horses.[217] Although the most consistent clinical sign is hirsutism, PU/PD may be reported in some horses. For example, in one review of 17 horses with Cushing's disease, PU/PD was found in 13 (76%).[218] However, in another series of 21 cases, PU/PD was not a historical complaint in any of the affected horses.[219] This discrepancy can be explained by the fact that PU/PD associated with Cushing's disease is generally of lesser volume than that observed with psychogenic polydipsia or diabetes insipidus.

Cushing's disease may lead to PU/PD by several mechanisms. First, polyuria may be the result of an osmotic diuresis. The renal threshold for glucose in horses (~150 to 175 mg/dL) appears to be lower than in small animals.[220] When plasma glucose concentration exceeds the renal threshold, the resultant glucosuria can lead to an osmotic diuresis. Although often implicated as the cause of PU/PD in horses with Cushing's disease, glucosuria was found in only one of five affected horses in one report.[219] Further, horses with hyperglycemia and glucosuria may still be able to concentrate their urine in response to water deprivation.[221] A second mechanism implicated in the development of polyuria is antagonism of the action of antidiuretic hormone (ADH) on the collecting ducts by cortisol. Although frequently cited as the mechanism of polyuria in canine hyperadrenocorticism, experimental evidence to support this mechanism is lacking in both dogs and horses. Further, there is considerable species heterogeneity in the effects of corticoids on ADH activity, and in some species a primary dipsogenic effect may be more important. Next, growth of the adenoma may lead to impingement on the posterior pituitary and hypothalamic nuclei (located immediately dorsal to pituitary gland), the sites of ADH storage and production, respectively.

Decreased ADH production and release would result in central diabetes insipidus as a third mechanism for polyuria.[217] Therefore, PU/PD seen in some, but not all, horses with pituitary adenomas is likely the combined result of several mechanisms.

34.19 PSYCHOGENIC POLYDIPSIA

Although rare, primary or "psychogenic" polydipsia is probably the most common cause of PU/PD in adult horses for which clients will have a primary complaint of excessive urination.[215,222] Horses with this problem are generally in good body condition and are not azotemic. Further, the magnitude of polyuria is typically dramatic, with owners reporting that horses drink two to three times more water than their stablemates, and stalls can be flooded with urine. In some horses, primary polydipsia appears to be a stable vice that reflects boredom, whereas in other cases it may develop after a change in environmental conditions, stabling, diet, or medication administration. Anecdotally, it has been reported to be more common in southern states during periods of high temperature and humidity.

The diagnosis of primary polydipsia is made by exclusion of renal failure and hyperadrenocorticism. In addition, other factors (e.g., salt supplementation, medication administration) must be excluded. Diabetes insipidus is excluded by demonstrating urinary concentrating ability after water deprivation.[223,224] Urine specific gravity should exceed 1.025 after water deprivation of sufficient duration (12 to 24 hours) to produce a 5% loss of body weight. In horses with long-standing polyuria, the osmotic gradient between the lumen of the collecting tubule and the medullary interstitium may be diminished (medullary washout). In these horses, ADH activity may not lead to an increase in urine specific gravity to values greater than 1.020. Consequently, in horses with primary polydipsia of several weeks' duration that fail to concentrate their urine after 24 hours of water deprivation, a modified water deprivation test may be tried. This is performed by restricting water intake to approximately 40 mL/kg/day for 3 to 4 days. By the end of this period, urine specific gravity should exceed 1.025 in a horse that has had medullary washout. If urine specific gravity remains in the isosthenuric range (1.008 to 1.014), the polyuric horse should be further evaluated for early CRF in which urine concentrating ability may be compromised before the onset of significant azotemia. In theory, this could occur when two thirds to three fourths of functional nephrons have been lost. Subtle signs of decreased performance and mild weight loss would also support early renal failure.

Management of horses with primary polydipsia is empirical. Because this is a diagnosis of exclusion, once it has been established that the horse does not have significant renal disease, it is safe to consider restricting water intake to meet maintenance, work, and environmental requirements of the horse. In addition, steps should be taken to improve the attitude of the horse by reducing boredom. Increasing the amount of exercise and turning the horse out to pasture are possible options, along with providing a companion or diversions in the stall. Also, increasing the frequency of feedings or the amount of roughage in the diet may increase the time spent eating and thereby reduce the habitual drinking.

In an occasional case of primary polydipsia, PU/PD may be attributed to excessive salt consumption and is manifested by an increased fractional sodium clearance.[214] Such "psychogenic salt eaters" appear to be less common than "psychogenic water drinkers" because the former would have to consume a substantial amount of salt to develop polyuria. In fact, salt intake may have to exceed 5% to 10% of dry matter intake before PU/PD becomes apparent.[225,226] Successful management consists of limiting water intake and preventing access to excess salt.

34.20 DIABETES INSIPIDUS

Diabetes insipidus (DI) may occur because of inadequate secretion of ADH (neurogenic DI) or decreased sensitivity of the epithelial cells of the collecting ducts to circulating ADH (nephrogenic DI).[212,213,227] With both forms of DI, dramatic PU/PD may be reported, and affected animals fail to concentrate urine in the face of water deprivation.

In human patients, neurogenic DI is the more common form of DI, with both hereditary and acquired forms described.[227] Two well-documented equine cases of neurogenic DI have been described.[228,229] Neither animal could concentrate urine in response to water deprivation, but administration of exogenous ADH resulted in an increase in urine specific gravity and decrease in urine volume. In a Welsh pony in which the condition was considered idiopathic, the absence of an increase in plasma ADH concentration after water deprivation further supported a diagnosis of neurogenic DI.[228] Acquired neurogenic DI secondary to encephalitis was confirmed histologically in the other horse.[229]

Nephrogenic DI is most often a familial disorder in humans, with an X-linked semirecessive mode of inheritance. [227] Therefore the disorder is carried by females and expressed in male offspring. Nephrogenic DI has been described in sibling thoroughbred colts, suggesting that an inherited form may also occur in horses.[230] These colts could not increase urine specific gravity in response to water deprivation, although they did show appropriate increases in plasma ADH concentration. A lack of response to exogenous ADH administration further confirmed resistance of the collecting ducts to ADH. Nephrogenic DI can also develop in association with drug therapy or a variety of metabolic, infectious, or mechanical (postobstruction) disorders. Anomalous or neoplastic disorders resulting in structural deformation of the kidneys are other potential causes of nephrogenic DI.[227]

944

945

After determining that an equine patient with PU/PD is not azotemic, the initial diagnostic test to differentiate DI from primary polydipsia is a water deprivation test.[228,229] However, horses with suspected DI should be monitored closely during water deprivation because affected horses will continue to excrete excess water in the face of water deprivation. As a result, they may become substantially dehydrated (10% to 15%) within the first 12 hours of water deprivation. When a patient fails to concentrate urine during water deprivation, neurogenic DI can be differentiated from nephrogenic DI by measuring plasma ADH concentration or by administration of synthetic ADH (as illustrated by the cases previously described). Currently, equine ADH cannot be measured at commercial laboratories, but synthetic ADH (60 IU every 6 hours IM or SC) can be administered in combination with monitoring urine specific gravity.

Treatment of DI is directed at managing PU/PD. With neurogenic DI, hormone replacement therapy with desmopressin (dDAVP, a potent ADH analog administered as eyedrops) has been a successful treatment in small animal patients.[231] However, this treatment has not been described in horses and may be cost prohibitive. With nephrogenic DI, hormone replacement therapy is ineffective, and the only practical form of treatment for many years has been to restrict sodium and water intake and to administer thiazide diuretics. The latter treatment may reduce polyuria by 50% in human and canine patients.[227,232] Thiazide diuretics inhibit sodium reabsorption in the distal tubule (diluting segment of nephron) and increase solute delivery to the collecting duct, but the mechanism by which such therapy benefits patients with nephrogenic DI is not well understood. Administration of prostaglandin inhibitors or amiloride may also decrease polyuria in patients with nephrogenic DI. The former agents probably work by decreasing renal blood flow and GFR, whereas amiloride, a sodium channel blocker, is thought to act similar to the thiazide diuretics.[216] No reports have documented the use of these treatments in horses.

34.21 DIABETES MELLITUS

Diabetes mellitus (DM) is a state of chronic hyperglycemia usually accompanied by glucosuria. The resultant osmotic diuresis is an occasional cause of PU/PD in horses and was described to result in a water intake in excess of 80 L/day in one report.[233] Type 1, or insulin-dependent, DM results from of a lack of insulin, which in human patients is usually attributable to viral or autoimmune disease. Individuals with type 2, or non-insulin-dependent, DM have normal to high insulin concentrations, but their tissues are insulin insensitive. The most common cause of equine type 2 DM is Cushing's disease, in which elevated plasma cortisol concentration appears to antagonize the effects of insulin. Although uncommon, there are a few reports of both type 1 and type 2 DM that were not caused by a pituitary adenoma and that resulted in PU/PD as one of the presenting complaints.[233–235]

34.22 SEPSIS/ENDOTOXEMIA

Polyuria and polydipsia have been described in horses with sepsis or endotoxemia, although other clinical signs (e.g., fever, abdominal pain, weight loss) predominate.[236] The mechanism of PU/PD is unclear but may result from endotoxin-induced prostaglandin production. Prostaglandin E_2 (PGE_2) is a potent renal vasodilating agent that can antagonize the effects of ADH on the collecting ducts.[237] Some horses with chronic gram-negative bacterial infections (e.g., peritonitis, pleuritis) may have low-grade or intermittent endotoxemia as a mechanism for PU/PD, similar to the polyuria observed with canine pyometra.[238]

34.23 IATROGENIC POLYURIA

A final cause of PU/PD may be iatrogenic as a result of several treatments. The most obvious iatrogenic cause is fluid therapy, for which polyuria is a desired response. Polyuria has also been observed with exogenous corticosteroid administration, although the mechanism remains unclear. Humans and dogs appear to experience a potent thirst response to exogenous corticosteroids; thus, polydipsia may be an important cause of the polyuria observed. In horses receiving chronic dexamethasone treatment for immune-mediated disorders, profound glucosuria (2 to 3 g/dL) may be observed and could lead to an osmotic diuresis. Finally, a transient diuresis or polyuria accompanies sedation with the α_2-agonists xylazine and detomidine.[239] Although these agents also cause transient hyperglycemia and occasional glucosuria, a more likely mechanism for the polyuria is existence of α_2-adrenoreceptors on collecting-duct epithelial cells. Activation of these receptors is another mechanism by which the action of ADH can be antagonized.[240]

34.24 RENAL TUBULAR ACIDOSIS

MONICA ALEMAN

Renal tubular acidosis (RTA) is a syndrome characterized by abnormal renal tubular function, which results in a hyperchloremic metabolic acidosis.[241–243] Hyperchloremia develops as a result of enhanced renal conservation of chloride consequent to bicarbonate loss. RTA can be categorized as *primary* (genetic or idiopathic) or *secondary* when attributed to an underlying disease process or drug administration. Drug-induced RTA has been documented in human patients after administration of amphotericin B, trimethoprim-sulfamethoxazole, outdated tetracyclines, gentamicin, cephalosporins, carbonic anhydrase inhibitors, lithium carbonate, and other organic compounds.

Three types of RTA have been described: I (distal), II (proximal), and IV (hyperkalemic distal).[241–243] Types I and II have been reported in dogs, cats, and horses. Type I develops when distal tubular excretion of hydrogen ions (H^+) becomes compromised, and affected patients are unable to produce acidic urine. Type II results from decreased proximal tubular bicarbonate resorption and subsequent loss of bicarbonate in the urine. Because H^+ ions are normally excreted as bicarbonate is reabsorbed in proximal tubules, acidosis with both type I and type II RTA results from decreased H^+ excretion. Type II RTA often is a self-limiting problem but may be accompanied by more widespread proximal tubular dysfunction, leading to defective resorption of glucose, amino acids, phosphate, potassium, sodium, calcium, magnesium, uric acid, and other organic acids. The latter disorder is known as *Fanconi's syndrome;* as with RTA, it may be a primary (inherited) problem or can develop secondary to kidney, metabolic, and autoimmune diseases or drug administration.[241–243] Although there are no well-documented reports, Fanconi's syndrome likely develops in an occasional horse as a sequela to nephrotoxic or vasomotor ARF. To date, type IV, or hyperkalemic distal, RTA has only been described in human patients.[242]

945

946

Renal tubular acidosis is a sporadically occurring metabolic disorder in horses.[244–247] There is no obvious breed or gender predilection, and to date, no evidence indicates that RTA is an inherited condition in horses. Typically, affected horses present with profound depression and anorexia and may have a history of poor performance, weight loss, and signs of abdominal pain. Vital parameters are generally within normal ranges, and horses do not appear clinically dehydrated. Hematologic and clinical chemistry findings are usually within reference ranges, with the exception of electrolyte concentrations and acid-base balance. A profound metabolic acidosis (plasma bicarbonate concentration <13 mEq/L and venous blood pH <7.25) and hyperchloremia (serum chloride concentration = 105 to 120 mEq/L) are characteristic for horses with RTA. A compensatory decrease in carbon dioxide partial pressure (P_{CO_2}) is also observed in most horses with RTA. Hypokalemia (and total body potassium depletion) may occur in horses with RTA because of the combined effects of anorexia and ongoing loss of potassium in urine, especially in patients with type II RTA, in which bicarbonaturia further increases urinary potassium excretion.

Mild to moderate azotemia may be detected in horses with RTA, especially when they are dehydrated at presentation. Affected horses may also have evidence of renal tubular damage detected on urinalysis (e.g., pigmenturia, glucosuria, abnormal sediment), and urine specific gravity may be low. Despite profound metabolic acidosis, urine pH is generally neutral to alkaline. If pursued, renal biopsy results generally support tubulointerstitial disease (CIN).

Differentiation of type I from type II RTA in human and canine patients is most easily accomplished by assessing urine pH; it remains neutral to alkaline with type I and should be neutral to acidic with type II.[241–243] Most horses with RTA have had neutral to alkaline urine; however, because herbivores normally have alkaline urine, this distinction may be less useful in horses with RTA. A few reports have described horses with acidic urine,[246,248,249] supporting type II RTA, but urine pH values near neutral are difficult to interpret. Assessment of all laboratory abnormalities (Table 34-1), along with additional testing (e.g., ammonium chloride challenge, urinary ammonium concentration) may allow further discrimination between type I and type II RTA.[249,250] However, this distinction may not be entirely necessary because the approach to treatment and the prognosis are similar for both types of RTA in horses.

Treatment of RTA consists primarily of IV and oral administration of sodium bicarbonate. Response to treatment appears to be largely dependent on the rate of $NaHCO_3$ administration. For initial correction of acidosis, IV $NaHCO_3$ must be administered aggressively, and large amounts (3000 to 9000 mEq) are often required to return plasma bicarbonate concentration to values above 20 mEq/L. Half the estimated bicarbonate deficit is generally

replaced with IV $NaHCO_3$ over 6 to 12 hours, and the remaining deficit is replaced with a combination of IV and oral $NaHCO_3$ (initial oral dose: 100 to 150 g twice daily; 1 g contains ~12 mEq $NaHCO_3$). Close monitoring of serum electrolyte concentrations and acid-base balance is required to adjust the rate of IV $NaHCO_3$ replacement. Marked improvement in attitude and appetite usually accompanies correction of the acidosis, but unfortunately, relapse after discontinuation of IV therapy can occur. Continued oral administration of $NaHCO_3$ (baking soda) for months to years may be required for maintenance of a normal acid-base status in individual horses.

Table 34-1 Classification of Type I and Type II Renal Tubular Acidosis

	Distal or Type I	Proximal or Type II
Acidosis	Severe	Self-limiting
Hypokalemia	Severe	Mild to moderate
Serum phosphate	Normal	Low
Urine pH	Neutral to alkaline	Neutral to acidic

Because potassium excretion is proportional to the bicarbonate delivery to the distal tubule, initial correction of acidosis with $NaHCO_3$ promotes kaliuresis and may exacerbate potassium depletion, especially when horses have been anorectic for several days. Therefore, concurrent supplementation with IV or oral potassium chloride is usually also necessary during initial correction of the acidosis. Complications associated with rapid correction of acidosis have not been described, but transient diarrhea may develop if large quantities of $NaHCO_3$ (>200 g) are given by nasogastric tube to horses that are completely anorectic.

Recurrence of metabolic acidosis also can occur when oral $NaHCO_3$ is discontinued. Relapses can be immediate or delayed for weeks to months, especially in horses that have RTA with evidence of renal damage. Reinstitution of $NaHCO_3$ supplementation usually corrects the metabolic abnormalities and accompanying depression and anorexia. The short-term prognosis for horses with RTA is good, and although the long-term prognosis has not been well documented, several horses have been reported to recover completely.[244–246]

34.25 BLADDER RUPTURE IN ADULT HORSES

THOMAS J. DIVERS

On rare occasions, bladder rupture may occur in adult horses. The problem often develops in association with urethral obstruction, foaling, or prolonged recumbency.[251] As azotemia develops, affected horses become depressed and inappetent. Clinical signs may not be apparent for several days, or stranguria may be observed, depending on the cause of the rupture. Abdominal distention is not as apparent in adult horses as in foals.

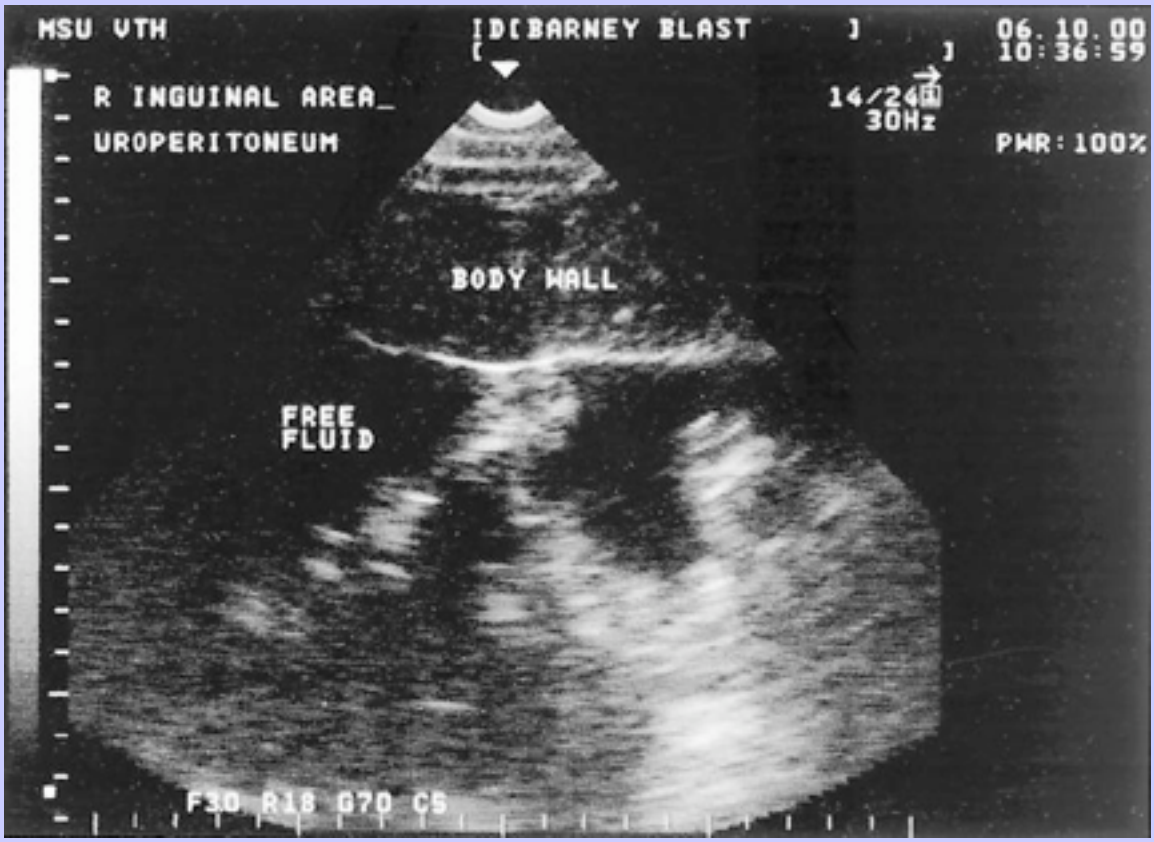
The diagnosis is based on history, rectal examination findings, laboratory results, and findings on ultrasonographic or cystoscopic examination. Postrenal azotemia develops within 24 hours after rupture and is accompanied by hyponatremia and hypochloremia. Unlike uroperitoneum in neonates, hyperkalemia is not a consistent finding. Transabdominal ultrasonographic examination of the abdomen reveals a large amount of peritoneal fluid (Fig. 34-15); abdominal fluid is easily recovered on abdominocentesis, and peritoneal fluid creatinine is twofold or greater than that of serum. Detection of calcium carbonate crystals on cytologic examination of peritoneal fluid is also diagnostic for uroperitoneum. Endoscopic examination of the bladder should allow determination of the

location and extent of the bladder tear. Rarely, uroperitoneum may also develop in some horses without full-thickness disruption of the bladder wall, and it is difficult to establish definitively the cause of uroperitoneum in these cases.

946

947

Fig. 34-15 Transabdominal ultrasonographic image of the right inguinal area of an adult horse with a ruptured bladder. A large amount of free hypoechoic fluid is apparent.



Surgical repair is indicated in horses with large tears in the ventral half of the bladder. In patients with small dorsal tears or incomplete tears, use of an indwelling bladder catheter (closed system) to keep the bladder small may allow the tear to heal without surgery.[252] Before surgery, IV fluids should be administered to correct dehydration, along with broad-spectrum antibiotics as prophylaxis against sepsis. If the abdomen is distended, urine accumulated in the abdomen should be removed (e.g., by placement of chest tube or other large catheter through ventral abdominal wall) before anesthesia is induced, to avoid further compromising respiration.

34.26 URINARY SYSTEM DISORDERS IN THE FOAL

THOMAS J. DIVERS

Umbilical disorders of the neonatal foal, including patent urachus, urachal infections, and omphalitis, are discussed in Chapter 19.

34.27 UROPERITONEUM

34.27.1 Bladder Rupture

The most common disorder of the bladder of otherwise healthy newborn foals is bladder rupture.[253–255] It is more common in colts, and clinical signs include repeated posturing to urinate and stranguria during the first 2 days of life. As urine accumulates in the abdomen, depression and abdominal distention typically develop between days 2 and 4. Repeated posturing and stranguria can easily be misinterpreted as tenesmus associated with meconium impaction (Fig. 34-16). Further, affected colts may continue to void small volumes of urine. Thus, establishing a diagnosis of a ruptured bladder can initially be challenging until more obvious signs of uroperitoneum (e.g., decreased nursing, abdominal distention) develop.

Laboratory findings in foals with uroperitoneum include hyponatremia, hypochloremia, hyperkalemia, and azotemia.[253–256] An occasional foal may also develop intermittent fine muscle tremors or a cardiac arrhythmia resulting from these electrolyte alterations, especially hyperkalemia. Transabdominal ultrasonographic examination usually reveals a large quantity of free fluid in the abdominal cavity, and peritoneal fluid creatinine/serum creatinine ratio greater than 2:1 confirms uroperitoneum.[253–256]

Fig. 34-16 A 2-day-old foal exhibiting stranguria caused by a ruptured bladder. Note the caudal position of the hindlegs, suggesting that the foal is straining to urinate rather than defecate. Differentiating between stranguria and tenesmus (meconium impaction) is not always easy.

Treatment of bladder rupture includes surgical closure of the defect, supportive care, and broad-spectrum prophylactic antibiotics for 3 to 7 days postoperatively.[253,254,256,257] An emergency surgical procedure is usually not required, and in most cases, surgery should be postponed for several hours until electrolyte abnormalities are partially corrected (most notably correction of hyperkalemia to a serum concentration <6.0 mEq/L). This can usually be accomplished by IV administration of 1 to 3 L of a 0.9% NaCl/5% glucose solution. Treatment with insulin should be avoided unless hyperkalemia is causing significant electrocardiographic (ECG) abnormalities and response to initial fluid therapy is poor. With marked hyperkalemia or abdominal distention causing respiratory embarrassment, slow drainage of urine from the abdomen (e.g., by chest tube or similar catheter) may be necessary before induction of anesthesia. Despite significant azotemia in some affected foals, use of aminoglycoside antibiotics is generally safe because the azotemia is postrenal rather than reflecting intrinsic renal disease. In most cases, placement of a urinary catheter to maintain an empty bladder for the initial 2 postoperative days is not necessary. However, uroperitoneum may recur after surgery in an occasional foal as a result of ongoing leakage from the bladder tear. When this complication occurs, it can usually be managed conservatively by placement of an indwelling bladder catheter (closed system) for 3 to 5 days. Rarely, a second celiotomy may be required.

34.27.2 Urachal Urine Leakage

Uroperitoneum may also develop in foals with urachal infection or ischemia. Affected foals are often septicemic or hospitalized for treatment of prematurity, hypoxic-ischemic encephalopathy, or botulism, and uroperitneum is recognized later (e.g., after 5 to 10 days of treatment).[257,258] Prolonged recumbency and bladder distention are likely risk factors. The umbilicus of many affected neonates appears normal during the first 2 days of life but, in some cases, may subsequently become patent. Urine leakage through the umbilicus may or may not be accompanied by leakage into the abdominal cavity or subcutaneous tissues of the abdominal wall. In other affected foals the umbilicus remains normal, and all urine leakage accumulates into the abdominal cavity. When monitored, inappropriate weight gain (e.g., >2 kg in 24 hours) is another common finding in hospitalized neonates that develop uroperitoneum.

947

948

Laboratory abnormalities typical for uroperitoneum may be found in affected foals but are not consistently abnormal because these patients are often being treated with IV fluids. Correction of the problem includes surgical removal of the diseased urachus, closure of the bladder apex, and continued supportive care for the primary disease. The prognosis for a successful outcome for these foals is not as favorable as for simple bladder rupture because they often have a degree of peritonitis (increasing risk for adhesions), and uroperitoneum is often only one of several complications of the underlying disease.[257,258]

In an occasional foal the urachus may also rupture more distally than usual and lead to subcutaneous accumulation of urine, ventral abdominal swelling, stranguria, signs of colic, and distress.[259] The swelling may be differentiated clinically from a hematoma or septic omphalitis because it may enlarge quickly and often becomes cold. Ultrasonographic examination and/or local aspiration of fluid and measurement of creatinine (twofold or greater than in serum) confirm the diagnosis. Prompt surgical removal of the leaking urachus is indicated.

34.27.3 Ureteral Defects

Ureteral defect(s) or disruption may also lead to development of uroperitoneum in both male and female foals.[260–263] Stranguria is usually absent, and urine initially accumulates in the retroperitoneal space, but with time the

retroperitoneal tissue ruptures, causing uroperitoneum. Affected foals may not be presented until 5 to 10 days of age because urine accumulation is slower than with a ruptured bladder. Clinical signs include decreased nursing, depression, and mild colic, and in fillies an external bulging of the vagina may be observed. Laboratory findings are typical for uroperitoneum, and with significant hyperkalemia, intermittent muscle fasciculations may be also noted.

If urine accumulation remains localized to the retroperitoneal space, ultrasonographic examination of the lower abdomen may be normal, but a large amount of retroperitoneal fluid will be detected around the kidney and upper flank (within retroperitoneal space) on the affected side(s). In addition, the renal pelvis may be mildly dilated.[264] If the peritoneal membrane is ruptured, physical and ultrasonographic examination findings are similar to those seen with a ruptured bladder, but careful ultrasonographic examination may also reveal a full bladder or concurrent retroperitoneal fluid accumulation. As with a ruptured bladder the ratio of retroperitoneal or peritoneal fluid creatinine/serum creatinine is greater than 2:1. In small foals (e.g., <50 to 75 kg), excretory urography (after IV administration of contrast agent) or pyelography (after percutaneous injection of contrast agent into renal pelvis with ultrasonographic guidance) may be useful for localizing the ureteral defect(s).

One or both ureters may be involved, and during surgical exploration, one or more defects can usually be found in the proximal half of the ureter, often near the renal pelvis. During surgery the defects can be localized by placing a catheter into the ureter through a cystotomy and injecting dye (e.g., Evans blue, methylene blue). Successful correction of unilateral and bilateral defects can be accomplished by placing a stent in the affected ureter(s) for 7 to 10 days.[260,261]

A report describing bilateral ureteral defects adjacent to the renal pelves provided histopathologic evidence that the lesions were traumatic in origin, rather than developmental anomalies.[263] The foal in that report had previously been kicked by its dam. The editor has also seen three foals with similar ureteral defects, all of which also had multiple rib fractures. Ureteropelvic junction injuries and proximal ureteral tears are a recognized complication after blunt abdominal trauma in human patients.[265] Taken together, these observations suggest that many ureteral defects in foals may more likely be traumatically induced at foaling, rather than being developmental anomalies.

34.28 CYSTITIS

Cystitis is rare in foals but can develop in recumbent premature or neonatal foals being treated with broad-spectrum antibiotics. Voided urine may have a characteristic flocculent consistency. When cystitis is suspected, the bladder should be catheterized and a urine sample submitted for urinalysis and quantitative culture. UTIs with *Candida* species are fairly common in recumbent neonates. Specific antimicrobial therapy is not usually necessary for *Candida* cystitis as long as systemic antibiotics can be discontinued. If antibiotic therapy continues, dissemination of the yeast infection can spread to other sites (e.g., joints).

34.29 SERUM CREATININE ELEVATIONS IN NEWBORN FOALS

During the first 1 to 3 days of life, creatinine concentration in newborn foals is often 30% to 40% higher than in their dams.[266] The cause is unclear but likely related to an inability of creatinine to equilibrate rapidly across placental membranes. As supportive evidence, creatinine concentration of normal amniotic fluid (that contains fetal urine) at term is approximately 10 mg/dL (and may exceed 30 mg/dL in some mares).[267] This transient increase in creatinine, which may occasionally exceed 20 mg/dL in premature foals, has been called a “spurious” elevation, but

this term should be discontinued because creatinine is truly increased. When an elevated creatinine level is detected in an otherwise healthy foal (that has also been observed to urinate normally), there may be no cause for alarm. However, if creatinine does not decline rapidly after birth or remains greater than 2.5 mg/dL on day 3 of life, peritoneal or retroperitoneal accumulation of urine, renal hypoplasia, or other causes of renal failure should be considered. Unlike creatinine, BUN values in foals are typically low (<10 mg/dL) after day 2 and remain low for the first several months of life. This finding can be attributed to the anabolic state of the growing foal.

Urinalysis results in normal neonatal foals are also different from those in adult horses. Specifically, normal foals may have marked proteinuria for 1 to 2 days after birth resulting from filtration of small—molecular-weight proteins absorbed with colostrum. Next, water intake on a predominantly milk diet (~250 mL/kg/day, compared with intake of 50 mL/kg/day of water by adults) is high in foals. As a result, after day 2 of life, urine is hyposthenuric (specific gravity, 1.002 to 1.006) and remains that way for several months. Finally, urinary enzyme activity and sodium and chloride clearances may be greater than adult values, and urine pH is neutral to acidic in foals.[268]

34.30 ACUTE RENAL FAILURE

Acute tubular necrosis is the most common pathologic lesion causing ARF in neonatal foals. Many cases develop during or after episodes of diarrhea, likely caused by poor perfusion (vasomotor nephropathy). Surprisingly, the diarrheal disease in some affected foals does not appear to be serious, but they may develop ARF. Similar to adult horses with ARF, the prominent clinical signs are depression and development of edema. Abnormal laboratory findings include azotemia, hyponatremia, hypochloremia, and hypocalcemia. Foals are more likely to develop significant hyperkalemia and hyperphosphatemia than adult horses with ARF. A urine specific gravity less than 1.018 and microscopic hematuria are usually also found in foals with ARF. Urine output of sick neonates should be monitored closely because they may become oliguric to anuric 12 to 24 hours before significant depression or azotemia is recognized. In addition, fluid retention during incipient ARF is another cause of inappropriate weight gain (e.g., >2 kg in 24 hours), which can often be detected before obvious edema develops.

948 949

Nephrotoxicity, most often from administration of aminoglycoside antibiotics or tetracycline, is another important cause of ARF (usually nonoliguric) in neonatal foals. As in adult horses, the recent change to once-daily aminoglycoside dosing appears to have decreased the incidence of hospital-acquired ARF in foals. However, it is important to remember that sick neonates are often more critically ill than many adult horses treated with aminoglycosides. Premature foals appear to be at even greater risk of nephrotoxicity than term foals. Judicious fluid therapy to correct dehydration and maintain blood pressure is an important precaution. Although there is a general impression that amikacin may be less nephrotoxic than gentamicin in foals, little supportive data exist. Regardless of which aminoglycoside antibiotic is selected, monitoring trough concentrations (<2 mg/mL for gentamicin; <4 mg/mL for amikacin) is warranted to decrease the risk of aminoglycoside toxicity in high-risk neonates. Dosage adjustment may be necessary in seriously ill neonates or premature foals because renal clearance may be decreased.[269]

The principles of treatment of ARF in neonates are essentially the same as those for adult horses (see earlier discussion). However, greater attention must be paid to monitoring responses to fluid therapy, including twice-daily measurement of body weight. Although foals that have a bout of ARF in the neonatal period would seem at greater risk of developing CRF later in life, no long-term follow-up study has corroborated this speculation.

34.31 SEPTIC RENAL DISEASE IN FOALS

Multifocal renal abscesses or infarct may be a complication of neonatal septicemia and can lead to ARF. *Actinobacillus equili* is the most common pathogen causing renal abscesses, but affected foals often die or are euthanatized because of overwhelming sepsis before clinical signs of ARF develop. Foals 2 to 4 days of age appear to be at greatest risk of developing acute *Actinobacillus* septicemia; when this problem is suspected, IV therapy with penicillin and gentamicin (at prolonged dosage) is recommended (see Chapters 18 and 20).

34.32 RUMINANT RENAL SYSTEM

34.32.1 ULCERATIVE POSTHITIS AND VULVITIS

DAVID C. VAN METRE

Ulcerative posthitis and vulvitis (enzootic balanoposthitis, pizzle rot, sheath rot) is an ulcerative bacterial infection of the mucous membrane and surrounding skin of the prepuce and vulva of small ruminants. The causative organism, *Corynebacterium renale,* inhabits the mucosal surface of the prepuce and vulva in low numbers. It proliferates and induces disease under conditions of high urea concentration in urine, which typically result from excessive dietary protein content. Losses result from debilitation caused by pain, incapacitation of breeding animals, loss of breeding soundness, and deformation of external genitalia. Venereal spread is possible.

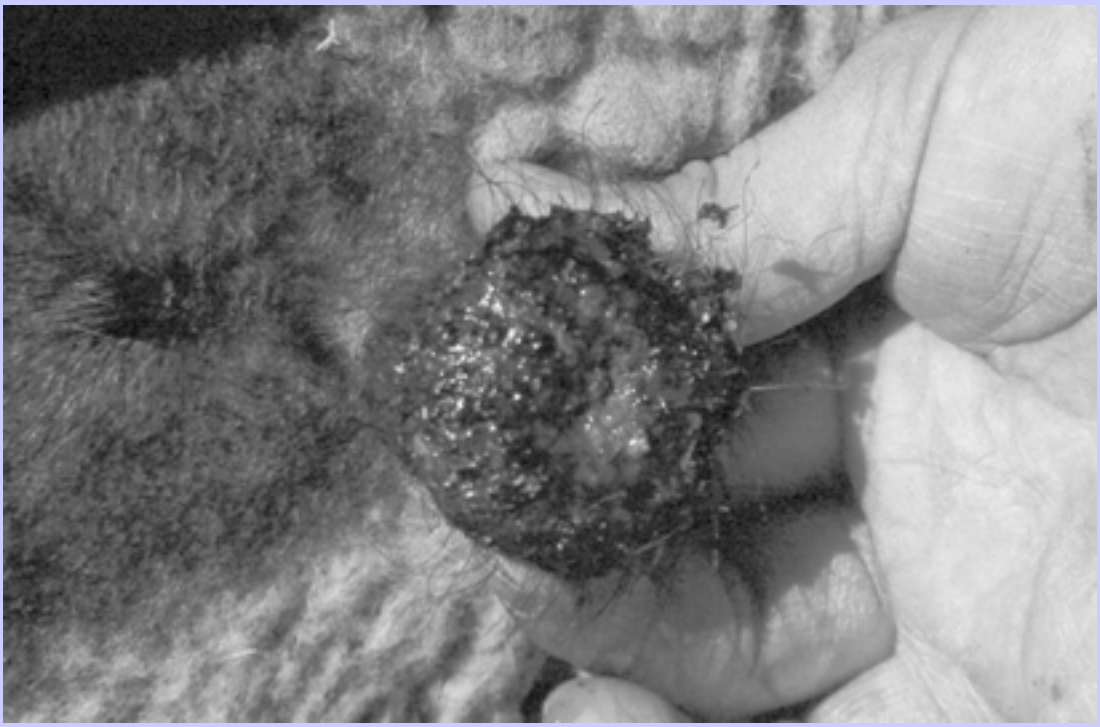
34.32.1.1 Clinical Signs

In rams, bucks, and wethers the infection begins as a moist ulcer, usually at or near the mucocutaneous junction of the prepuce. The ulcer surface is soon covered with a thin, loose, brown to red, malodorous scab (Fig. 34-17). If the scabs are removed, little or no hemorrhage will occur from the underlying tissue.[1] Focal swelling is often noticeable at the cranial aspect of the prepuce, and the area is usually painful on palpation.

If unchecked, the infection may spread along the mucosal surface inside the prepuce, creating the more serious internal form of ulcerative posthitis. In such cases the entire prepuce may be swollen and elongated. Affected animals often show dysuria, and goats may vocalize during voiding. Weight loss may occur in chronic cases. As local inflammation progresses, ulceration of mucosal surfaces may result in fibrous adhesions between the penis and prepuce. Severe inflammation of the glans penis may cause stricture of the urethral process *(pizzle)* and restriction of urine egress. Impairment of breeding soundness may result from admixing of blood or exudate into the ejaculate, penile adhesions, cicatricial scarring of the preputial orifice, or suppurative urethritis; pain may limit libido as well.

Ulcerative lesions of similar appearance can develop on the vulva and perineum of affected ewes and does. Gross vulvar enlargement may be noticed from a distance. Dysuria may result from involvement of the urethral orifice. The fibrosis and contracture that develop in chronic, severe cases may distort normal vulvar conformation to the point of impairing copulation or partuition.

Fig. 34-17 Ulcerative posthitis in a Suffolk ram.



34.32.1.2

Differential Diagnosis

Ulcerative dermatosis (lip and leg ulcer) is a dermatitis of sheep caused by an unclassified poxvirus related to the parapox virus of contagious ecthyma.[2] Infection with this agent may manifest as balanoposthitis and vulvitis, and the crusted ulcers that develop closely resemble those induced by infection with *C. renale*. Removal of the crusts overlying ulcerative dermatosis lesions may reveal a granular lesion that bleeds readily. The genital form of ulcerative dermatosis occurs most often in the fall breeding season in the western United States. Ulcers on the lips, nares, coronets, and interdigital spaces may also be present.[2] Contagious ecthyma *(orf)* occasionally affects the genitalia and perineum, although lesions are much more frequently found on the lips, face, and udder. These lesions are raised, appear proliferative, and are covered with a thick, durable scab. Urolithiasis must be considered strongly in the differential diagnosis of any dysuric male or castrated male small ruminant. Although rare in small ruminants, preputial trauma, particularly if resulting from entrapped grass awns, can cause preputial swelling, pain, and exudation within the preputial cavity. External ulcerative lesions would not be expected in such cases.

Caprine herpesvirus 1 (CHV-1) was isolated from aborted fetuses in three separate California goat herds.[6] A buck on the premises had shallow, red, irregularly shaped ulcers in its prepuce that tested positive for CHV-1 on polymerase chain reaction (PCR). Biopsy of the ulcers revealed intranuclear inclusion bodies within the stratum spinosum of the preputial epithelium.

34.32.1.3

Pathophysiology

C. renale is an aerobic, gram-positive, pleomorphic, club-shaped bacterium that is a normal inhabitant of the skin and external genitalia of small ruminants.[3,4] This organism is capable of surviving in wool and scabs from lesions for as long as 6 months and can survive freezing temperatures in lesion exudate.[5] *C. renale* is capable of hydrolyzing urea. Experimental diversion of urine flow has demonstrated that the presence of urine is required for both induction of and maintenance of lesions on the genitalia.[3] The organism proliferates on the genital mucosal surface in response to elevated urinary concentration of urea. Diets high in crude protein or nonprotein nitrogen increase the urinary urea content and are required for development of the disease.[1,5] *C. renale* hydrolyzes urea to ammonia, which causes ulceration of the prepuce and surrounding skin.

34.32.1.4

Epidemiology

This condition appears to be more common in males and wethers than in females.[1] Lambs under 6 months of age can occasionally be affected,[5] but given the relatively short lifespan of market lambs, the disease is most often recognized in rams, Angora wethers, and pet wethers. Although all breeds are susceptible, higher rates of this disease are found in Merinos and Angoras.[1,7] Because of the dense wool and hair coat of these breeds, urine soaking near the preputial orifice may increase the local concentration of urea. Seasonal differences in the incidence of the disease are thought to reflect shearing schedules and changes in the availability of high-protein diets.[1]

Because the organism is part of the normal skin and genital flora, disease can occur in isolated individuals under proper dietary conditions. However, the disease is contagious, because transfer of necrotic debris from the ulcers of affected animals can induce the disease in normal animals.[1,5] Venereal transmission of the disease has been documented. Several months may pass between the exposure of ewes to infected rams and the development of vulvitis in ewes.[5]

34.32.1.5

Treatment and Prevention

Affected animals should be isolated to limit venereal or contact transmission. Wool or hair should be removed from the skin surrounding the prepuce or vulva, and a topical antibiotic may be applied. Caustic antiseptic solutions should not be used. Treatment with systemic antibiotics is indicated for advanced cases or for outbreaks, in which handling of several animals for topical therapy is not feasible. Penicillin is the antibiotic of choice, although tetracycline has provided favorable results. Treatment should continue until the lesions have dried and acute inflammation has subsided.

Reduction of protein and nonprotein nitrogen intake is crucial for successful treatment of affected animals and for prevention of additional cases.[1,5] Dietary crude protein levels of 16% to 18% (or higher) predispose sheep and goats to ulcerative posthitis and vulvitis.[1] Reduction of dietary protein alone may result in satisfactory cure if the lesions are early in development. Shearing, especially at the time of highest protein intake, may be efficacious in reducing disease incidence.[5] Incorporation of grass hay feeding into a program of legume pasture grazing may help limit protein intake.

Surgical treatment of advanced cases has been described.[8] The procedure involves resection of ventral preputial tissue to allow for normal urine flow and, less often, successful return to breeding.

34.32.1.6 Prognosis

Response to treatment is optimal early in the infection, before deformation of the prepuce and vulva as a result of fibrosis. The chances for full recovery without recrudescence are poor if dietary protein intake is not reduced. Complete recovery of breeding soundness is unlikely in animals with internal ulcerative posthitis.

34.33 UROLITHIASIS

JENNIFER M. MACLEAY

Urolithiasis is a common metabolic disease occurring in most mammalian species. Uroliths cause disease through trauma to the urinary tract and obstruction of urinary outflow. Calculi (uroliths) most often lodge in the urethra, although obstruction of the bladder trigone, ureters, or renal pelvis can also occur. Sequelae to urinary tract obstruction include urethral perforation and rupture, urethral stricture, bladder rupture, ureteral rupture, hydroureter, hydronephrosis, and rarely, rupture of the kidney(s). Urolithiasis can occur in outbreaks or as an endemic problem in group-housed animals or as an individual disorder in animals kept as pets. A definitive diagnosis of urolithiasis in a single animal suggests that all males in the population are at risk for the disease, because of the importance of dietary and environmental factors in its pathogenesis.[9]

34.33.1 HISTORICAL FINDINGS

The clinical signs of urolithiasis can vary; duration, extent (complete vs. partial), and location of the obstruction determine the historical and examination findings. The early clinical signs can be remarkably subtle and may include anorexia, depression, and mild bloat. A history of colic and straining to urinate or defecate may be provided, and novice owners often mistake stranguria for constipation or tenesmus. To aid in the diagnosis, suspected cases can be placed in a dry, unbedded stall to allow for assessment of urine output.

34.33.1.1 Acute Urethral Obstruction

34.33.1.1.1 Clinical Findings

Impacted calculi lead to urethral trauma and progressive bladder distention, resulting in strangury and abdominal pain. Affected animals may be restless, tread, swish their tails, and or grind their teeth. Goats and camelids may vocalize. Stranguria is manifested as repetitive bouts of stretching and contraction of the abdominal muscles. Straining may induce secondary rectal prolapse; therefore, urethral obstruction should be investigated as the primary disease in cases of rectal prolapse. Rarely, affected calves develop a visible dilation of the urethra at the midline of the perineum proximal to the obstruction.[10] Tachycardia, tachypnea, and mild bloat secondary to ruminal stasis are more common findings. Anuria occurs if urethral obstruction is complete, whereas urine may dribble in cases of partial obstruction. If a urine sample can be collected for dipstick analysis, proteinuria and occult hematuria are frequently detected. Crystals or blood may be found on the hairs of the preputial tuft; in cases of anuria the hairs are dry. Fever is usually absent.

The lumen of the bovine urethra narrows at the distal aspect of the sigmoid flexure, near the level of insertion of the retractor penis muscles.[11,12] Calculi most frequently become lodged at this site in cattle,[11–14] and pain or focal swelling over this area may be appreciated. Rectal examination (digital rectal examination in small ruminants) often reveals pulsation of the pelvic urethra. In cattle, bladder distention is palpable rectally except in cases of complete obstruction complicated by rupture of the urethra or bladder.

Abdominal palpation is useful in affected small ruminants, small camelids, and pot-bellied pigs. The examiner should place the fingertips of each hand into the ventral flank on each side of the abdomen. While slowly pressing the fingertips toward midline in the caudal abdomen, the examiner may encounter an orange- to grapefruit-sized, firm, spherical structure, which is the distended bladder (Fig. 34-18). Severe bladder distention will not be palpated in cases of incomplete urethral obstruction or bladder rupture.

The urethral process (pizzle) is the most common site of calculus impaction in sheep and goats and should be examined in suspected cases of urolithiasis.[14,15] Sedation or general anesthesia facilitates extrusion of the penis for examination. Because of its diuretic effect, xylazine may exacerbate bladder distention and is not recommended. Diazepam (0.1 mg/kg IV slowly) or acepromazine (0.05 to 0.1 mg/kg IV or IM) have been used successfully, either as sole agents or in combination with butorphanol (0.05 to 0.1 mg/kg IV). Alternatively, in hemodynamically stable individuals, it is possible to induce light general anesthesia with isoflurane.

Fig. 34-18 Palpation of the bladder of a Barbados wether.

An adjunct or alternative to sedation is administration of epidural anesthesia, which provides greater patient comfort and eliminates muscular resistance to penile extrusion. One milliliter of 2% lidocaine per 5 kg of body weight is injected into the epidural space at the lumbosacral junction.[16] Lower dosages may provide sufficient anesthesia. The total dose should not exceed 15 mL of 2% lidocaine in any small ruminant, regardless of size.[16] If cerebrospinal fluid (CSF) is obtained, one half of the epidural lidocaine dosage can be administered as a true spinal block. Hindlimb motor blockade, potentially lasting for several hours, is expected with either epidural or true spinal anesthesia at this site.

To exteriorize the penis, the sheep or goat is propped up on its rump. The examiner can then exteriorize the penis by pushing the sigmoid flexure cranially from the base of the scrotum while pulling the sheath caudally. Small towel clamps or Allis tissue forceps can be used to apply traction to the penis. In many cases, preputial mucosa must be carefully grasped and extruded before the penis can be reached with a second pair of forceps. The urethral process can then be inspected and palpated for the presence of discrete uroliths or sandlike grit within the lumen. If the urethral process is obstructed, it can be amputated with scissors or a scalpel blade (see Surgical Treatment).

34.33.1.1.2

Differential Diagnosis

Tachycardia, colic, bloat, and anorexia are characteristic of gastrointestinal (GI) obstruction, but auscultation and percussion of the abdomen, abdominal succussion, rectal examination, and abdominal ultrasonographic examination should differentiate this condition from acute urethral obstruction. Goats with grain overload will occasionally vocalize and show signs of colic.[17] Encephalopathies, salmonellosis, coccidiosis, and proctitis from rectal prolapse or trauma frequently cause tenesmus. Additional signs of primary neurologic or GI dysfunction should be evident with these diseases.

Although rare in male ruminants, primary urinary tract infection (UTI) may result in dysuria and pollakiuria. Bladder distention is uncommon with UTI, and large numbers of white blood cells (WBCs) and bacteria are present in the urine sediment. Occasionally an animal with urolithiasis successfully voids the obstructing urolith(s). The resultant traumatic urethritis might cause dysuria, but the rate and ease of urination typically improve over time and with antiinflammatory treatment.

In younger animals, it is important to consider congenital abnormalities, such as ectopic ureter(s), pelvic displacement of the urinary bladder, and urethral duplication. Congenital abnormalities may be manifest at birth or not until later, depending on the level of observation and whether the defect results in obstruction, partial obstruction, or constant urine dribbling.

34.33.1.2

Urethral Rupture

Urethral rupture is a common complication of urethral obstruction in cattle. The wall of the obstructed urethra undergoes pressure necrosis, causing leakage of urine into the subcutaneous tissue of the perineum and ventral abdomen. Sequelae include cellulitis, penile adhesions (possibly creating phimosis), and urethral stricture. Erection failure secondary to vascular obstruction of the corpus cavernosum of the penis has been reported as a sequela to urethral obstruction and rupture in a goat.[18]

34.33.1.3 Clinical Findings

951

952

Affected animals are frequently depressed and inappetent and have bilaterally symmetric, pitting edema in the ventral perineum, inguinal region, prepuce, and ventral abdomen (Fig. 34-19). Swelling of the abdominal wall may extend as far forward as the axillae. The affected areas are initially warm and painful on palpation. As necrosis progresses, the tissues become cool, dark, nonpainful, and potentially gangrenous. A fistula may develop to allow urine to escape. Fever may occur if tissue necrosis and sloughing are extensive. Rectal examination in steers and bulls reveals a small bladder.

Fig. 34-19 Urethral rupture in a Holstein steer. Tissue swelling from urine accumulation may extend to the sternum and axillae.

34.33.1.4 Differential Diagnosis

Ventral abdominal swelling is found with umbilical or scrotal hernias with or without concurrent subcutaneous infection. These conditions can be differentiated from urethral rupture by careful palpation of affected tissues and through ultrasonography to identify defects in the body wall or presence of bowel in the swelling. Pain and heat are more pronounced in local infection than in urethral rupture. Aspiration of subcutaneous fluid with cytologic examination is helpful in identifying primary infectious processes. In bulls, penile hematomas may cause localized swelling of the prepuce in the prescrotal region and caudal sheath; unlike urethral rupture, however, the swelling does not involve the ventral abdominal wall. Aspiration of a suspected penile hematoma is not recommended because of the risk of iatrogenic infection.

34.33.2 Rupture of the Bladder (Water Belly)

In all ruminants and camelids, prolonged bladder distention secondary to urethral obstruction may result in pinpoint perforations, tears, or necrosis of large areas of the bladder wall. In cows, bladder rupture may also occur as a rare complication of dystocia.[19,20] Rupture of a urachal remnant may also result in uroperitoneum.[21] The dorsum of the bladder fundus is the most common site for rupture,[14] but rupture in other bladder regions does occur.[22]

34.33.3 Clinical Findings

Relief of bladder distention causes cessation of stranguria. Bilateral distention of the ventral abdomen develops within 1 to 2 days after rupture and is accompanied by worsening clinical signs of depression, anorexia, weakness, dehydration, and shock. Ballottement of the abdomen may elicit a fluid wave. Rectal temperature may be normal,[23] but shock may result in hypothermia. The animal's breath may smell like ammonia. On rectal or abdominal palpation, the bladder is small or not palpable. Ultrasonography of the abdomen reveals a large volume of free fluid and a collapsed or partially filled bladder. Abdominocentesis yields a large volume of blood-tinged fluid. The fluid may or may not smell like urine and can be warmed to aid in detection of the urine smell. Measurement of creatinine in the fluid can be used to confirm a diagnosis of uroperitoneum (see Clinical Pathology). On occasion, urine translocation into the thoracic cavity can occur, presumably by passage across the diaphragm. Uremia and dehydration result in debilitation and eventual death if medical and surgical treatments are not provided.

34.33.4 Differential Diagnosis

Seepage of urine across the bladder wall and into the abdominal cavity may occur in cases of severe bladder distention; in such cases, rupture is often imminent. Ventral abdominal distention may develop with diffuse peritonitis, vagal indigestion, or ascites secondary to liver fibrosis, caudal vena caval thrombosis, or hypoproteinemia. Marked peritoneal cavity effusion may be found in cases of mesothelioma. These conditions are differentiated from bladder rupture through rectal examination, ultrasonography, cytologic and chemical analysis of peritoneal fluid, evaluation of serum chemistry, and abdominal exploratory surgery.

34.34 Chronic Partial Urethral Obstruction

An uncommon form of urolithiasis, chronic partial urethral obstruction occurs if calculi impair but do not completely obstruct urine outflow.[24] Chronic retention of urine elevates fluid pressure within the urinary tract lumen, potentially leading to hypertrophy of the bladder wall, hydroureter, and hydronephrosis. Azotemia, progressive renal failure, and uremia are evident in cases that develop hydronephrosis.

34.35 Clinical Findings

Affected animals have been termed “dribblers” because of their characteristic slow or intermittent urine flow during voiding.[25] Lethargy, reduced appetite, and thin body condition are evident if renal failure has developed. On rectal examination the bladder may be small, and thickening of the bladder wall may be palpable.[24]

34.36 Differential Diagnosis

Urine dribbling may also occur in animals with neurologic disease caused by previous urethral trauma (stricture formation), congenital anomalies of the urogenital tract, chronic infection, or neoplasia. Contrast urethrography may be used to identify the presence of strictures or anomalous structures. Small ruminants with the internal form of ulcerative posthitis may dribble urine. In such cases, characteristic preputial lesions are present. Tumors of the urinary tract, although rare compared to urolithiasis, may cause gradual obstruction in cattle, small ruminants, and camelids.

34.37 Ureterolithiasis and Nephrolithiasis

34.37.1 Clinical Findings

Cattle with acute ureteral obstruction may show severe colic with stretching, kyphosis, treading, collapse, and vocalization.[25] Signs of distress may be less severe or even absent if obstruction is intermittent or incomplete.[26] Enlargement of the blocked ureter may be palpated rectally, and if the left ureter is obstructed, enlargement of the left kidney may be appreciated. Azotemia is most severe if the obstruction is bilateral. Rarely, pyelonephritis is the inciting cause of ureteral obstruction, because necrotic debris and calculi may be released into the ureter from the infected renal pelvis. Pyelonephritis can also be a consequence of ureteral[26] or renal[27] calculosis. With ureteral or renal rupture, uroperitoneum or retroperitoneal accumulation of urine may occur.

952 953

34.37.2 Differential Diagnosis

Signs of abdominal pain or colic can result from GI or urinary tract obstruction in ruminants and camelids. Auscultation and percussion of the abdomen, rectal examination findings, ultrasonography, or radiography may allow for differentiation of GI obstruction from ureteral or renal obstruction. Cases of ureteral or renal calculosis without colic may show nonspecific signs of illness, and serum chemistry, urinalysis, and ultrasound examination may be useful for definitive diagnosis.[26]

34.37.3 Ancillary Diagnostic Tests

34.37.3.1 ULTRASONOGRAPHY/RADIOGRAPHY

A presumptive diagnosis of urolithiasis can usually be made through historical and physical examination findings. Ultrasonographic or radiographic evaluation of the urinary tract may allow for confirmation of a diagnosis.[28–31] In cases of prolonged urethral obstruction (≥48 hours) or urethral obstruction with severe azotemia, it is prudent to perform ultrasonographic examination of the kidneys before consideration of surgical treatment. Detection of severe hydronephrosis warrants a poor prognosis for recovery.

Ultrasonographic evaluation of the bladder of pot-bellied pigs, small ruminants, and camelids is most easily accomplished through transabdominal scanning with a 3.5- or 5.0-MHz sector-array probe, directed caudodorsally from the inguinal area. Both kidneys of small ruminants and camelids and the bovine right kidney can be examined from the right paralumbar fossa.[28] In cattle, transrectal examination of the pelvic urethra, bladder, ureters, and left kidney is performed with a 7.5-MHz linear-array probe. Marked distention of

the bladder, thickening of the bladder wall, and echogenic material within the bladder lumen may be seen with acute urethral obstruction. A large volume of free fluid in the abdomen is characteristic of uroperitoneum and is suggestive of existing or impending rupture.

Radiographic examination of the urinary tract is limited to thin, pot-bellied pigs, camelids, small ruminants, and young cattle. Radiodense calculi in the bladder may be most easily detected with lateral views of the abdomen, taken with the animal in lateral recumbency with the hindlimbs pulled caudally. Positive-contrast urethrography allows for detection of radiolucent urethral calculi, urethral stricture, or urethral rupture. After catheter placement about 5 cm into the penile urethra, injection of a volume of 10 to 30 mL of water-soluble contrast media has been used with success in adult bucks and rams. Accidental introduction of bubbles may complicate interpretation of urethrograms; to avoid this problem, the catheter should be completely filled with contrast material before insertion. Injection should be performed slowly with minimal pressure to avoid iatrogenic urethral rupture.

34.38 CLINICAL PATHOLOGY

34.38.1 Acute Urethral Obstruction

Hematologic and serum chemistry findings may be unremarkable in ruminants with acute urethral obstruction uncomplicated by urethral or bladder rupture.[15] Hyperglycemia and a stress leukogram may be present. With time, hemoconcentration and azotemia develop secondary to reduced water intake. Azotemia is severe in cases of hydronephrosis. Hematuria and proteinuria are consistent abnormalities, whereas crystalluria is a variable finding.[32] Pyuria is present with traumatic urethritis, cystitis, or secondary bacterial infection.

34.38.2 Bladder Rupture

Bladder rupture and accumulation of urine in the abdomen result in more profound alterations in hematologic and serum biochemical parameters. Urine osmolality is normally two to three times that of extracellular fluid (ECF), and ruminant urine contains higher concentrations of urea, creatinine, and potassium but lower concentrations of sodium and chloride than ECF.[23,33] Therefore, movement of water, urea, and electrolytes occurs along diffusion gradients, resulting in hyponatremia, hypochloremia, hyperphosphatemia, uremia, and hemoconcentration.

Serum potassium concentration in ruminants with bladder rupture may be more variable, depending on appetite and time before diagnosis. Potassium values tend to be normal or low in cattle with bladder rupture, even if uroperitoneum exists for several days.[23] Anorexia may contribute to hypokalemia or normokalemia in these cases, and aldosterone release secondary to volume depletion results in dramatic increases in salivary potassium excretion, providing an alternative route of potassium excretion in affected cattle.[19] Once in the GI tract, potassium absorption may be diminished by ileus and preferential absorption of sodium over potassium.[20] Alkalosis, which occurs secondary to hypochloremia, may also serve to reduce ECF potassium concentration by encouraging movement of potassium intracellularly.[23]

Although only a small fraction (≤10%) of phosphorus excretion in the ruminant is urinary,[20] hyperphosphatemia may occur secondary to uroabdomen. Potential mechanisms for hyperphosphatemia include phosphorus diffusion from the urine into the ECF, reduced glomerular filtration, and tissue hypoxia causing breakdown of

organic phosphate compounds in cells.[23,34] In addition, reduced salivary flow from anorexia may limit phosphorus excretion in the saliva, contributing to phosphorus retention.[20] Anorexia, ileus, and a competitive effect of hyperphosphatemia may contribute to reduction in serum calcium concentration in cases of uroabdomen.[23]

Chemical analysis of peritoneal fluid is a useful means of documenting uroabdomen. Creatinine is a relatively large, polar molecule that does not readily move back into the ECF space despite its high concentration in the abdomen. Therefore, peritoneal fluid creatinine can be compared to serum creatinine concentration, with a peritoneal fluid/serum ratio of 2:1 indicating uroabdomen.[23]

Uroabdomen is often associated with a chemical peritonitis. However, experimentally induced bladder rupture did not cause peritonitis in steers, even after several days of uroperitoneum.[23] Nonetheless, WBC count and blood fibrinogen levels may increase in cases of ruptured bladder, possibly reflecting more extensive tissue necrosis and inflammation in natural cases. With uremia, impairment of blood coagulation may become an important clinical consideration. Reduced platelet aggregation and alteration of coagulation factor function occur in uremic patients of other species.[34] Bleeding diathesis and elevation of partial thromboplastin time (PTT) have been reported in azotemic cattle.[35]

34.38.3 Urethral Rupture

Leakage of urine into the subcutaneous space produces hematologic and serum biochemical alterations that are similar but less severe than those seen with bladder rupture.[33] The muscles and subcutis holding the urine do not possess as large a surface area as the peritoneal cavity. Therefore, less rapid and less extensive fluxes of water, ions, and waste products occur.[33] Tissue necrosis and secondary infection may result in neutrophilia, leukocytosis, and hyperfibrinogenemia.

953

954

34.38.4 Chronic Partial Obstruction

Hyponatremia, hypochloremia, hypocalcemia, hyperphosphatemia, and severe azotemia with isosthenuria suggest extensive nephron damage caused by hydronephrosis.[24]

34.38.5 Necropsy Findings

When the urethra is opened along the sagittal plane, hemorrhage and necrosis of the urethral mucosa are evident at the site of obstruction. Particular attention should be paid to examination of the distal urethra in camelids, the urethral process in sheep and goats, and the sigmoid flexure in cattle. Calculi may be relatively large, discrete mineral aggregates or very fine and sandlike. Calculus material should be collected for analysis of mineral composition. Occasionally, no calculi can be found in the urinary tract, but mucosal trauma and necrosis of the bladder or urethra persist.

Urethral rupture is characterized by the subcutaneous accumulation of urine in the inguinal area, prepuce, and ventral abdomen and hemorrhage at the site of the urethral defect. In cases of bladder rupture the abdominal cavity is filled with a large volume of blood-tinged fluid. Defects in the bladder wall vary in size and location, and necrosis of large areas of bladder wall may be present.[22] In rare cases the bladder wall is intact but obvious

uroabdomen exists, suggesting transmural seepage of urine. Hydronephrosis, hydroureter, and bladder wall hypertrophy may be present in animals with chronic partial urethral obstruction.[24]

34.38.6 Treatment and Prognosis

34.38.6.1 SALVAGE

Steers and feeder lambs may be sent for immediate slaughter if urethral obstruction is diagnosed before development of azotemia or urinary tract rupture.[36]

34.38.6.2 MEDICAL TREATMENT

Medical treatment of urolithiasis is aimed at relief of the obstruction and correction of any fluid and electrolyte abnormalities. The antispasmodic effect of certain tranquilizers may facilitate passage of a urethral obstruction.[9] Relaxation of the retractor penis muscle, which results in straightening of the sigmoid flexure, is another means by which these drugs may facilitate passage of calculi.[13] In small ruminants, however, medical treatment with intravenous (IV) fluids, nonsteroidal antiinflammatory drugs (NSAIDs), or tranquilizers alone has not met with much success, and surgical intervention is recommended.[15,37]

34.38.6.3 SURGICAL TREATMENT

Surgical treatment of urolithiasis is dictated by economic considerations, intended use of the animal, available facilities and equipment, and status of the patient. Removal or bypass of the obstruction and restoration of urine output are the goals of surgical treatment. The prognosis for both short-term and long-term survival will vary according to the patient's status and the surgical procedure chosen. Acute renal failure is an occasional sequela to urinary tract obstruction and should be considered in the prognosis.

34.39 PREOPERATIVE CONSIDERATIONS

Ruminants and camelids with urinary tract obstruction, particularly those with uroperitoneum, often require preoperative stabilization of hypovolemia and correction of electrolyte abnormalities, particularly if surgery is to be performed under general anesthesia or with the animal restrained in recumbency. Fluid therapy should be guided by analysis of serum electrolyte concentrations. An initial bolus of hypertonic (7%) saline followed by physiologic (0.9%) saline solution can be used to correct intravascular volume deficits, hyponatremia, and hypochloremia. Calcium salts can be added to the fluids if indicated. Empirical supplementation of IV fluids with potassium should be avoided because the potential for hyperkalemia always exists. Hyperkalemia can induce fatal cardiac dysrhythmias, and this effect is augmented by concurrent hyponatremia.[38] Administration of dextrose, sodium bicarbonate, and/or insulin (regular insulin at 0.25 to 0.4 U/kg IV slowly, SC, or IM) reduces serum potassium concentration by promoting movement of potassium from the extracellular to the intracellular space. Blood glucose should be closely monitored when insulin is administered. Uremic animals undergoing IV fluid therapy may develop pulmonary edema,[39] so attention must be paid to respiratory rate, auscultatory findings, and respiratory effort during fluid therapy. Slow drainage of urine from the abdominal cavity reduces pressure on the diaphragm and slows the progression of metabolic derangements caused by uroperitoneum. In long-standing cases of uroabdomen, urine may also be present in the thorax, further warranting close observation of respiratory function

during anesthesia. Thoracocentesis to remove thoracic urine is indicated if respiratory function is compromised; otherwise, abdominal drainage usually induces resolution of thoracic urine accumulation.

Although bacterial infection is not considered to be a common primary cause of urolithiasis, secondary UTIs may develop after surgical intervention. Loss of the flushing effect of urination, urinary mucosal damage, impaired host cellular defenses secondary to uremia, and indwelling urinary catheter placement may contribute to the development of ascending UTI. Perioperative antibiotic therapy is therefore prudent, with due consideration of withholding times in animals intended for slaughter. Postoperative antibiotic therapy is discussed later.

34.40 SURGICAL OPTIONS

Surgical options include amputation of the obstructed urethral process, penectomy, perineal urethrostomy, prepubic urethrostomy, urethrotomy, cystotomy, tube cystostomy, and bladder marsupialization. Urethral catheterization and retrograde flushing have been used to dislodge urethral calculi and restore urine flow in a ram.[40] However, successful clearance of the urethra is rarely achieved,[15] and retrograde flushing under pressure may result in urethral rupture. Retrograde passage of a catheter may allow for localization of the urethral obstruction, potentially guiding further surgical treatment. Passage of a catheter into the bladder of ruminants and camelids is difficult because of the presence of a urethral recess located near the ischial arch.[41]

In sheep and goats, *amputation of an obstructed urethral process* is a simple procedure that may at least temporarily restore urethral patency. The urethral process can be removed without detrimental effects on breeding soundness.[42] Success rates for initial restoration of urine flow after urethral process amputation range from 37.5%[32] to 66%.[15] However, recurrence of urethral obstruction is extremely common, and urethral patency is often maintained for only hours to days before reobstruction occurs.[15,32] Therefore, urethral process amputation is palliative and may provide enough time to allow feeder lambs to survive until slaughter. For pet wethers, rams, and bucks, recurrence of urinary tract obstruction appears to be probable if this is the only procedure performed.

Penectomy is an option for animals intended for slaughter. *Perineal urethrostomy* is a surgical option for ruminants not intended to be used for breeding. In small ruminants, postoperative stricture of the stoma or recurrent obstruction with additional calculi is a long-term risk.[15,43] *Ischial urethrostomy* with placement of a Foley catheter into the bladder has been used as a treatment for urolithiasis in heavy feedlot steers[44] and bulls.[12] If urethral damage is not severe, this procedure allows the breeding ability of bulls to be maintained.[12]

Prepubic urethrostomy has been reported in a sheep and a goat.[45] In this procedure a midperineal penectomy is performed. The perineal segment of the penis and pelvic portion of the urethra are dissected free from the surrounding soft tissue using perineal and ventral celiotomy incisions, respectively. Bilateral ileal and ischiadic osteotomies may be required to free the pelvic urethra. The urethral mucosa is then sutured to the skin of the caudoventral abdomen to create a long-lasting stoma.

Urethrotomy (removal of obstructing calculi and primary closure of urethra) is another option.[12,14] The calculi may be located, crushed with a towel clamp, and flushed from the urethral lumen, eliminating the need for a urethral incision.[12,14] Urethral stricture, adhesions resulting in phimosis in breeding males, and reobstruction with additional calculi are long-term complications.

Cystotomy allows for maintenance of breeding soundness and removal of additional calculi from the bladder. In small ruminants and camelids, bidirectional (normograde and retrograde) flushing is used to restore urethral

patency.[15,32] Even if the urethra is successfully cleared of calculi, traumatic urethritis may cause significant postoperative dysuria in these animals. Therefore, some surgeons prefer also to perform a tube cystostomy to allow for rest and healing of the irritated urethra.[46] If the urethra cannot be cleared at surgery, the tube cystostomy allows for the urethra to rest, and spontaneous elimination of calculi often occurs. Alternatively, a percutaneous tube cystostomy could be performed under ultrasound guidance.

Tube cystostomy allows urine to exit the bladder through a temporary Foley or other type of suprapubic catheter, which is anchored in the bladder lumen and exits the ventral abdomen.[37,47] Urethral patency is apparently restored when calculi are spontaneously expelled from the urethra, dissolved, or refluxed into the bladder, at which time the catheter can be removed. In cases of urethral rupture where patency of the entire urethra is the preferred outcome, tube cystostomy is often the sole feasible option.[46] Primary repair of the urethral defect is rarely successful because of swelling and maceration of the damaged mucosa.

Contrast medium can be introduced into the bladder through the catheter to monitor urethral patency, locate urethral obstruction, or identify urethral rupture.[29] In a goat with a tube cystostomy, 30 mL of a commercially available urinary lavage product containing citric acid, glucono-delta lactone, and magnesium carbonate (hemiacidrin; Renacidin, Guardian Laboratories, Hauppauge, NY) was infused through the cystic catheter and left in the bladder for 30 minutes four times daily for 3 days.[48] This solution is acidic (pH 3.85) and was used to facilitate dissolution of calculi.

Spontaneous resolution of urethral obstruction with tube cystostomy may take several weeks or longer; a mean time of about 11 days in small ruminants has been reported.[37,47] To judge when removal of the catheter is appropriate, the cystic catheter can be clamped shut and the animal observed for urination through the urethra.

Complications of tube cystostomy have been reported to be as high as 50% with surgically placed tube cystostomies and 100% with percutaneously placed cystic catheters.[49] The primary complication is a dislodged catheter, the replacement of which necessitates a second surgery. Risk of tube dislodgement appears to be less when 18 to 20 French tubes are used, when the tube has a balloon to retain the catheter in place (Foley-type catheter), and when a purse-string suture is used in the bladder wall.[47,49] Other complications encountered include tears of the bladder, leakage of urine into the abdomen, adhesions of the bladder to intestine or body wall, and obstruction of the catheter.

In cases of bladder rupture, the urine should be drained from the abdominal cavity, and a surgical procedure should be performed to divert urine to the exterior. If primary repair of the bladder defect is desired, a laparotomy and cystotomy or tube cystostomy can be performed with the animal under local[22] or general[50] anesthesia. Primary repair of the bladder defect is not always necessary, however, because spontaneous sealing of the bladder with fibrin or omentum can occur. Depending on the size and location of the bladder defect, daily or continuous abdominal drainage may need to be performed until spontaneous sealing occurs. Tears are more likely to seal spontaneously if they are located on the dorsal aspect of the bladder[51]; however, it is generally difficult to know the location of the bladder defect without performing a laparotomy. Abdominal drainage may be combined with perineal urethrostomy or penectomy.[12–14] Alternatively, a catheter can be secured in the bladder by a small abdominal incision[52] or an ischial urethrotomy.[12,44]

In *bladder marsupialization* the apex of the bladder is exteriorized using a small paramedian incision, and the seromuscular layer of the bladder is circumferentially secured to the abdominal wall. A cystotomy is performed, and the bladder mucosa is secured to the skin, creating a permanent opening for urine drainage from the bladder to

the exterior.[53] Advantages of bladder marsupialization include decreased hospitalization time and expense for the owner. However, complications include chronic urine scalding, stricture formation, reobstruction, and bladder prolapse. Failure of bladder marsupialization was reported to be 33% in one study.[49]

Ureteral calculi may be removed by *ureterotomy*.[14] *Nephrectomy* may be performed in unilateral cases of obstructive nephrolithiasis.[54] If unilateral nephrectomy is under consideration, measurement of BUN, serum creatinine, and urine specific gravity, with or without a biopsy of the apparently unaffected kidney, should be performed to evaluate remaining renal function.[55] Normal urine specific gravity, BUN, and serum creatinine indicate that the majority of nephrons in the remaining kidney are functional.

Multiple small stab incisions into the skin and subcutaneous tissue along the ventral abdomen may facilitate urine drainage in cases of urethral rupture. These are allowed to heal by second intention.

34.41 POSTOPERATIVE CONSIDERATIONS

Continued assessment of hydration, urine output, and serum urea nitrogen, creatinine, and electrolyte concentrations is indicated after surgery. Postobstruction diuresis has been reported in ruminants[40] and may result from tubular damage, accumulation of urea or natriuretic factors, or preoperative fluid therapy.[56] Induction of modest diuresis through fluid therapy after surgery may help to reduce azotemia and accumulation of blood clots and bacteria in the urethra.

Antimicrobial therapy with an antibiotic that achieves high urine concentrations (e.g., penicillin, ampicillin, sulfonamides) is warranted; the duration of therapy depends on the surgical procedure chosen, residue withholding considerations, and whether UTI exists at surgery. For tube cystostomy, antimicrobial therapy is recommended while the tube is in place and for at least 1 week after the tube is removed.[37] Antimicrobial therapy should be maintained for at least 3 weeks after surgery in animals with active UTI.

Prompt initiation of preventive dietary and environmental management is critical for the long-term success of any surgical procedure for urolithiasis (see Prevention). In animals intended for slaughter, at least 30 days is often required for resolution of tissue damage from urethral or bladder rupture.[44]

34.41.1 Epidemiology

34.41.1.1 GENDER

Obstructive urolithiasis in ruminants and camelids is almost exclusively a disease of males and castrated males. Urinary calculi appear to develop to a similar degree in female ruminants. However, most calculi can pass through the relatively short, distensible urethra of the female, making urethral obstruction uncommon.[57]

Calculi form to a similar extent in the urinary tracts of bulls and steers. Because of the trophic effect of testosterone, the urethral diameter of yearling bulls is approximately 25% greater than that of yearling steers. Urethral obstruction therefore is more common in steers.[11] A similar predisposition for urethral obstruction may exist for wethers relative to buck goats.[49] However, because many wethers are kept as pets, factors such as diet, environment, and age are likely to differ compared with bucks. Specific gender risks in camelids and

pot-bellied pigs is not well described; in commercial pigs, urolithiasis is generally associated with husbandry problems such as improper calcium/phosphorus ratio in the ration and inadequate water availability.[58]

34.41.1.2 SEASON

The incidence of urolithiasis increases in the late fall and winter in North America.[57] Limited water availability, increases in the silica content of range grasses, and a larger population of susceptible animals (young, growing males) during this time of year may be responsible for this trend. In warmer climates, urolithiasis is more frequently a problem in the arid months of the year, underscoring the role of water intake in the pathogenesis of the disease.[57]

34.41.1.3 AGE

Cattle of various ages may develop obstructive urolithiasis. The tendency for this disease to be seen in younger ruminants may be the result of dietary influences, because younger animals are more often fed concentrates for weight gain and eventual slaughter than are mature males kept for breeding. In addition, because relatively fewer mature males are kept for breeding, the apparently increased prevalence of urolithiasis in younger animals may simply reflect the greater numbers of younger males and castrated males at risk.

34.41.1.4 SILICA UROLITHIASIS

Estimates of annual death losses in steers in western North America range from 3%[44] to 5%.[57] Deaths and treatment costs attributable to silica urolithiasis in cattle have been estimated to cost Canadian ranchers $500,000 to $1 million per year (1981 Canadian dollars).[57] Silica urolithiasis is a very common subclinical condition in certain areas. For example, in western North America, silica calculi can be found in the urinary tracts of 50% to 80% of range cattle, with urinary tract obstruction occurring in a variable percentage of these animals.[57,59]

34.41.1.5 PHOSPHATIC UROLITHIASIS

In one study the prevalence of urolithiasis was 0.5% and 0.35% for two Colorado lamb feedlots.[60] The calculus types in these lambs were not identified and are assumed to have been phosphatic calculi. Urolithiasis was the fifth most prevalent cause of death on each feedlot.[60] In beef feedlots, death losses from urolithiasis have been estimated at 0.6%.[61]

34.41.2 Pathophysiology

34.41.2.1 MECHANISMS OF CALCULOGENESIS

Multiple factors influence the development of urinary calculi, but of primary importance is the development of high urinary concentrations of soluble, ionized minerals *(crystalloids)* that aggregate to form insoluble crystals. Supersaturation of urine with a calculus-forming crystalloid is a prerequisite for urolith development.[62] However, supersaturation alone is not solely responsible for urolith initiation because normal urine is

typically supersaturated with a variety of calculogenic ions.[63] Urine contains variable concentrations of mucopolysaccharides, ions, and organic acids, which act as intrinsic inhibitors of crystallization. Through physical and electrochemical interactions, these compounds maintain calculogenic minerals in a colloidal suspension. Calculus formation is initiated if supersaturation of urine with appropriate crystalloids exceeds the protective capabilities of the crystallization inhibitors. The crystalloids are rendered insoluble and precipitate out of the aqueous phase of urine. Calculi enlarge as further mineral precipitation takes place on the crystal surfaces. Dietary, environmental, and management influences interact to determine the degree of supersaturation of urine with calculogenic minerals. Dehydration, with resultant concentration of urinary minerals, would appear to be a potential contributing factor in the development of all types of uroliths.

Mucoproteins, which make up a variable fraction of most uroliths, may act as templates (matrices) on which calculogenic ions could initiate crystallization.[62] Urine mucoproteins may reduce the solubility of certain crystalloids or may be passively incorporated into developing uroliths.[64,65] Estrogenic substances in the diet may promote urolithiasis by increasing urinary mucoprotein concentration.[65,66] This was of particular concern in the past, when diethylstilbestrol (DES) was used as a growth promoter in sheep and cattle in North America.[66]

The solubility of some calculogenic crystalloids is influenced by urinary pH. Struvite (magnesium ammonium phosphate), calcium phosphate, and calcium carbonate uroliths are less soluble in alkaline urine, whereas calcium oxalate solubility is not affected by changes in urine pH within the physiologic range.[63,67–69] The effect of urinary pH on silica calculi is debatable,[70] but recent findings show a trend toward reduction in formation under conditions of mild aciduria.[71]

Primary UTI is considered an uncommon cause of ruminant urolithiasis.[68] Purulent debris within the urinary tract may serve as a nidus for crystal development, and bacterial ureases may increase urinary pH, thereby reducing the solubility of certain crystalloids. Pyelonephritis, with presumed secondary urolithiasis, has been reported in cattle.[26] Urolithiasis may be considered as both a rare cause[27] and a rare consequence[26] of UTI.

Although rare, vitamin A deficiency has been incriminated as a contributory factor for urolith development.[68] Metaplasia of urinary tract epithelium may create nidi for calculogenesis through desquamation of cells or altered cell surface characteristics.

Feeding patterns may influence the formation of urinary calculi. In ruminants, providing a ration in one or two feedings per day induces antidiuretic hormone (ADH) release soon after feeding, resulting in a marked but transient decline in urine output and an increase in urine concentration.[14,57] These changes in urine composition can be limited through ad libitum feeding.[9] Water hardness (dissolved mineral content) has not been considered a significant factor in ruminant urolithiasis.[57]

34.41.2.2

PHOSPHATIC UROLITHIASIS

Ruminants consuming rations high in phosphorus, such as grain-based feedlot rations, typically develop struvite calculi[9,68,72–75] or calcium phosphate (apatite) calculi.[58,76] Rations where the calcium/phosphorus ratio favors phosphorus are particularly prone to cause outbreaks of urolithiasis.[58,75] Increased dietary phosphorus levels result in increased concentration of phosphate ion in ruminant urine.[72] Because calcium opposes phosphorus absorption from the gut, urinary excretion of phosphate is augmented by low dietary

levels of calcium relative to phosphorus.[68,72,73] The interaction of magnesium with calcium and phosphorus is less clearly understood,[72] but experimental increases in dietary magnesium levels to 0.6% of dietary dry matter induced calcium phosphate and struvite urolithiasis in calves.[74] 956 957

Pelleting of rations has been associated with an increased incidence of phosphatic urolithiasis.[9] Ruminant saliva is rich in phosphorus, and the GI tract is the primary route of phosphorus excretion in ruminants.[20] In theory, ruminants feeding on pelleted rations produce less saliva, which would reduce GI phosphate losses and increase urinary phosphate excretion.[9]

34.41.2.3

SILICA UROLITHIASIS

Silica urolithiasis is primarily a problem of sheep and cattle grazing native rangeland grasses of western North America. The silica fraction of these grasses tends to increase with maturity and may continue to increase even after growth ends. In some areas, 4% to 8% of total grass dry matter may be silicon compounds.[57] A fraction of dietary silica, as unpolymerized silicic acid, is dissolved in the ruminal fluid of the grazing animal, absorbed, and excreted in the urine. In sheep and cattle on range, water intake is usually intermittent. During periods of water deprivation, avid water and sodium resorption by the kidneys results in the formation of highly concentrated urine. Silicic acid may be concentrated to such an extent that it polymerizes to a less soluble form, polysilicic acid. Polysilicic acid, in turn, forms large micelles in solution that quickly become insoluble when bound to urinary mucoproteins.[64] The resultant calculi are usually composed of about 20% mucoprotein, 75% silicon dioxide, and variable amounts of calcium oxalate and calcium carbonate.[57]

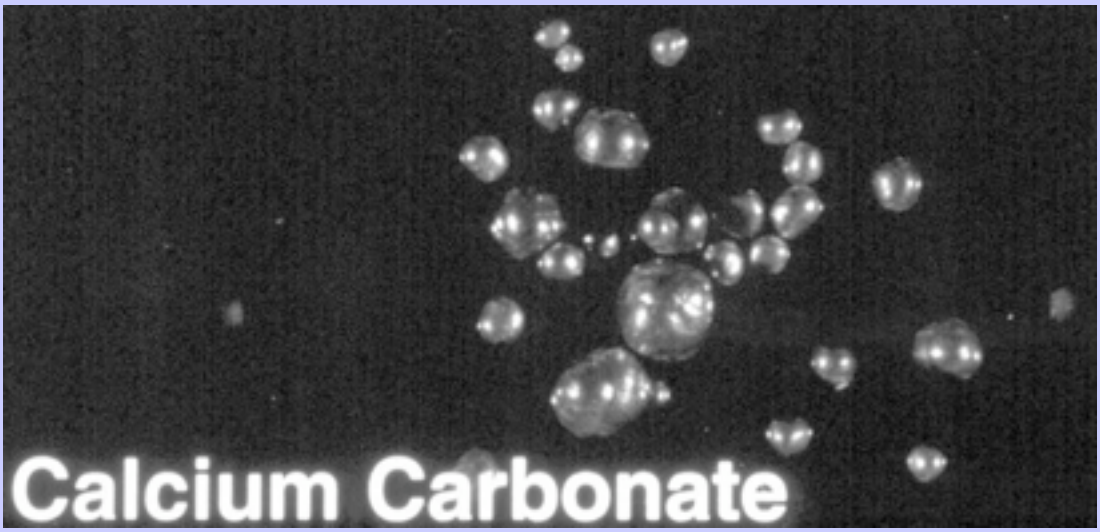
Dietary deficiencies of copper and zinc have been identified as contributory factors in silica urolith formation in rats.[77] The incidence of silica urolithiasis can be increased by feeding sheep rations that have a high calcium/phosphorus ratio (~2.8:1) and induce more alkaline urine.[71,78] It is important to note that a high calcium/phosphorus ratio in the diet can help to prevent one type of urolith (struvite) but may be a contributory factor for another (silica). This underscores the importance of both ration and urolith mineral analyses in the formulation of preventive measures for this disease.

34.41.2.4

CALCIUM CARBONATE UROLITHIASIS

Calcium carbonate calculi have a characteristic round shape and golden color and are often present as multiple calculi scattered throughout the lower urinary tract (Fig. 34-20). These calculi are common in sheep grazing lush, rapidly growing clover pastures in Australia.[69] These forages are rich in calcium and low in phosphorus and magnesium and have high oxalate content. In the gut, oxalate avidly binds calcium and makes it unavailable for absorption. With gradual introduction of oxalate-rich diets, ruminal bacteria efficiently metabolize oxalate to bicarbonate.[69,79] Thus, microbial metabolism of oxalate in the rumen may increase the availability of dietary calcium.[80] These factors may combine to increase urinary calcium excretion and alkalinize urine, thereby promoting calcium carbonate calculogenesis. Calcium carbonate urolithiasis has been reported in northern California.[81] Although many of the animals in this report had a history of being fed alfalfa hay, the relationship, if any, between alfalfa feeding and calcium carbonate urolithiasis remains unclear.

Fig. 34-20 Calcium carbonate calculi.



34.41.2.5 CALCIUM OXALATE UROLITHIASIS

Oxalate is an end product of glycine and ascorbic acid metabolism and is a normal constituent of urine.[62,69] In humans, inherent defects in oxalate metabolism and calcium homeostasis contribute to calcium oxalate urolithiasis.[62] Dietary and metabolic factors that influence formation of this urolith type have not been elucidated in ruminants. Poisoning by oxalate-containing plants is not considered a common cause of calcium oxalate urolithiasis.[68] Given its very low solubility, calcium oxalate crystals are often present in normal urine[68] and may be incorporated into other uroliths as a trace component.

34.41.3 Prevention

A preventive approach to a urolithiasis problem begins with a search for risk factors associated with the diet, management, and the environment. Whenever possible, ration analysis and mineral analysis of the urolith(s) should be performed to identify causative dietary factors accurately. Consult Box 34-1 for analysis laboratories. If uroliths are not obtained, ration analysis and a thorough dietary history may provide a strong suggestion of the urolith type. In light of the central role of urinary supersaturation in calculogenesis, the ultimate aim of preventive measures should be reduction of urinary concentration of calculogenic mineral ions. In addition, the urine should be diluted to such an extent that the calculogenic ions are less prone to precipitate. Dilution of urine is achieved through increased salt and water intake.

34.41.3.1 DIETARY MANAGEMENT

34.41.3.1.1 Phosphatic Urolithiasis

Prevention of phosphatic calculi requires adjustment of the dietary calcium/phosphorus ratio to a level of 2:1 or greater.[72] The magnesium content of the ration should be maintained at recommended levels. Abandoning pelleted feeds and increasing the quantity of long-stem forage in the ration may increase salivary flow and fecal phosphate excretion.[9]

Addition of salt to feedlot rations has proved effective in several studies. Sodium chloride, fed at a level of 3% to 5%, reduces the incidence of urolithiasis without adverse effects on feed intake or weight gain.[64] Cattle consuming such rations show variable increases in water intake and urine output, implying that some

of the beneficial effect of salt feeding results from diuresis.[57,82] Other studies show minimal effect of this level of salt supplementation on urine volume, and one investigator has suggested that the preventive effect is caused by interruption of crystal development by chloride ion in urine.[66] Nonetheless, it is prudent to anticipate increased water intake after salt supplementation is initiated.

Ammonium chloride supplementation, fed at a level of 0.5% to 1% of ration dry matter, also reduces the incidence of struvite urolithiasis.[82,83] Ammonium chloride may increase the solubility of magnesium ammonium phosphate crystals through a modest reduction in urinary pH. The pH of the urine is likely to be influenced by the relative concentrations of strong cations (sodium and potassium) and strong anions (chloride and sulfate) of the entire ration, a relationship termed the *dietary cation-anion difference*.[84] Thus the efficacy of ammonium chloride in reducing urinary pH and therefore reducing struvite urolithiasis may vary among different livestock operations because the concentration of these cations and anions may vary among rations.[81]

34.41.3.1.2

Silica Urolithiasis

Restriction of dietary silica intake in ruminants grazing native grasses is not feasible; thus dietary management is limited to salt (sodium chloride) supplementation. However, loose salt or lick salt is unlikely to be ingested in sufficient quantities to affect water intake.[85] Sodium chloride supplementation of palatable creep feeds, at a level of 15% of dry matter, is an effective measure for range calves.[57] Creep feeding should begin at 4 months of age or earlier. Initially, lower salt concentrations may be required for young calves to become accustomed to the feed. The feeders should be located near a reliable source of palatable water.

Ammonium chloride supplementation (1% of dry matter) has been demonstrated to significantly reduce silica urolith development in lambs.[78] In the same study, reduction of the dietary calcium/phosphorus ratio from 2:1 to almost 1:1 resulted in a trend toward reduced silica calculi formation. The role of copper and zinc deficiencies in ruminant silica urolithiasis remains to be determined.

34.41.3.1.3

Calcium Carbonate Urolithiasis

This type of urolith has been frequently recovered from small ruminants fed alfalfa hay.[81] Because of this and the risk factors identified in Australian sheep, reduction of dietary calcium levels could be beneficial. This may not be possible for sheep grazing legume pastures. Ammonium chloride supplementation may be an effective preventive measure because calcium carbonate is more soluble in acidic solutions.[69]

34.41.3.2

WATER MANAGEMENT

Maximizing water intake is an important aspect of urolithiasis prevention, regardless of the urolith type involved. Cleaning of water containers should be a regular practice. Water palatability may also be improved through provision of shade for water containers during the summer. Dark liners (with sun exposure) or heaters will warm water during the winter. Automatic waterers should be checked regularly for proper function. Shallow containers capable of rapid refilling provide higher rates of water turnover, resulting in less stagnation.

In operations involving multiple animals or large pastures, placement of multiple watering sites might allow for more frequent intake. This is especially true for sheep, whose banding instinct usually prevents individuals from traveling alone to distant watering sites.

34.41.3.3

URACHAL DISORDERS

ROGER W. ELLIS

Abnormalities of the umbilicus and umbilical remnants, including the urachus, are frequently encountered disease conditions of neonatal calves. Infections of the umbilicus, urachus, and umbilical vein or arteries *(navel ill)* are often associated with localized or systemic bacterial infections acquired from environmental contamination at birth. The association of umbilical abnormalities with calfhood morbidity and mortality has been established.[86] Of the umbilical structures, the urachus is most frequently involved.[87,88] Occasionally, more insidious and chronic conditions of the urachal remnant are observed in older calves and mature cattle. Internal abscessation, adhesions, sepsis, peritonitis, uroperitoneum, cystitis, and intestinal strangulation have all been reported.[89–94] Urachal fistulas or acquired patent urachus, although often observed in foals, is infrequently reported in cattle.[95]

34.41.3.3.1

Pathogenesis

Subsequent to bacterial infections of the urachus of the neonate, the inflammatory response within the abdomen precipitates development of fibrinous adhesions between the urachus and surrounding viscera, including the rumen, intestine, uterus, bladder, or ovaries. Abscesses may form in single or multiple locations in the urachal stalk; although uncommon, abscesses involving the apex of the urinary bladder result in concurrent cystitis.[91,94] Urachal fibrosis and adhesions may serve as a means of mechanical interference of bladder emptying, resulting in secondary cystitis from chronic urine retention.[94] Infrequently, the urachal abscess perforates, with subsequent peritonitis, sepsis, or uroperitoneum.[89,90] Most urachal infections involve *Arcanobacterium pyogenes* or *Eschericia coli*; other skin or enteric organisms may be present as well.[96]

Alternatively, the urachus may fail to regress completely, creating a persistent communication between the bladder apex and the pouchlike urachal remnant. The volume of urine retained in the urachal remnant is variable. Animals with this problem may remain asymptomatic for life; however, retention of urine in the urachal “pouch” can predispose the animal to urinary tract infection. Further, rupture of the urachal remnant can occur, resulting in uroabdomen and, if cystitis is also present, septic peritonitis.[89]

34.41.3.3.2

Clinical Findings

Calves with internal urachal abscesses, adhesions, and other sequelae are usually older than 4 weeks of age. A history of umbilical infection during the neonatal period may or may not exist, and external umbilical abnormalities may not be present. Clinical signs may be nonspecific, including fever, lethargy, poor body condition, and poor growth or productivity. Dysuria, pollakiuria, stranguria, and colic may be evident on examination or may be included in the medical history. External palpation of the umbilicus and abdomen in smaller calves may reveal pain and enlarged umbilical remnants, particularly in the caudoventral abdomen along a line from the umbilicus to the pelvic brim. Diarrhea, abdominal distention, and an ached-back

stance may be evident in animals with concurrent peritonitis. Complications from associated septicemia, such as lameness and joint distention, pneumonia, hypopion, and meningitis, are occasionally seen. When infection extends into the bladder lumen, hematuria and pyuria are reliably present.[91,94]

In older animals, spontaneous rupture of the infected urachal stalk may result in the acute onset of peritonitis. If the urachal remnant communicates with the bladder lumen, rupture of the urachus results in uroabdomen. Rupture may occur spontaneously or after abdominal trauma or parturition. Transrectal palpation may allow detection of abnormal bladder size, position, or shape resulting from adhesion of the bladder apex to the urachal remnant. Distention or displacement of bowel may be detected in cases of urachovisceral adhesions.

958

959

A detailed ultrasonographic examination of the interior of the umbilical remnant is warranted. Transrectal and transabdominal ultrasonographic examination of the caudal and ventral abdomen may reveal structures compatible with urachal abscesses. The bladder and other viscera may assume abnormal shape or position as a result of urachal adhesions.[91,97] The luminal contents of the urachal remnant and bladder may appear flocculent in cases complicated by concurrent cystitis. Uroabdomen is characterized by accumulation of echolucent fluid in the abdominal cavity, with variable amounts of fibrin deposition evident.

In cases complicated by urachal infection or peritonitis, laboratory findings of an inflammatory hemogram, including leukocytosis, neutrophilia, hyperfibrinogenemia, and hyperglobulinemia are expected. Urinalysis may be normal or indicative of cystitis if the urinary bladder is involved. Abdominocentesis findings are variable and depend on the presence and extent of peritonitis associated with the urachal lesion. Voluminous, blood-tinged abdominal fluid suggests uroperitoneum, and analysis of the fluid and serum creatinine concentration is indicated (see Urolithiasis).

34.41.3.3.3

Differential Diagnosis

Because of the variable nature of urachal problems, the differential diagnosis will vary according to the organ(s) involved. The general clinical picture may suggest acute, subacute, or chronic infection with involvement of the abdomen and lower urinary tract. Urachal adhesions to the intestine or uterus may result in colic, signs of intestinal obstruction, and postpartum peritonitis or uroabdomen. Concurrent signs involving the lower urinary system might indicate the potential for primary ascending infections, such as cystitis or pyelonephritis. In cases of uroabdomen in males, obstructive urolithiasis is an important differential. Urolithiasis, urethritis, or neurologic disease may be included in differential diagnoses of dysuric animals. Nephritis of hematogenous origin is worthy of consideration in animals showing ill-thrift, colic or an arched back, or abnormal urine.

34.41.3.3.4

Treatment

Ventral midline celiotomy, paramedian celiotomy, or laparoscopy under general anesthesia is recommended to enable complete evaluation of the abdominal cavity.[98,99] Resection of the urachal remnants with careful dissection of adhesions is often required for complete resolution. Resection of the apex of the urinary bladder is necessary if the urachus incorporates or communicates with the bladder. Perioperative and postoperative antibiotic therapy is essential, and appropriate antibiotic selection may be based on culture and sensitivity of the abscess(es) or urine.

34.41.3.3.5 Prognosis

Outcomes of the surgical management are often satisfactory, but recurrence of adhesions should always be considered as a potential outcome. A guarded to poor prognosis is warranted for severe peritonitis or extensive adhesions. Without surgery, medical management with long-term antibacterial therapy would be expected to provide limited success because the structural problems created by adhesions and abscesses are not directly addressed.

34.41.4 EVERSION OF THE BLADDER AND PROLAPSE OF THE BLADDER

DAVID C. Van METRE

Eversion of the bladder is an uncommon event that occurs during or shortly after parturition in cows.[100–104] Forceful straining moves the bladder fundus caudally, eventually turning the bladder inside-out. The bladder is then forced out of the urethral orifice. Prolapse of the bladder is also a rare periparturient event in cattle, more frequently associated with dystocia.[100,101] In this condition a full-thickness tear of the vaginal wall occurs during delivery, allowing the bladder (and possibly other viscera) to be displaced from the abdominal cavity into the vagina.

34.41.4.1 Clinical Findings and Differential Diagnosis

Cows with either eversion or prolapse of the bladder have a smooth, spherical mass within the vagina, usually protruding from the vulva. An affected cow may be alert and ambulatory, but if concurrent hypocalcemia, exhaustion, or peritonitis exists, the cow may be recumbent and depressed. Careful vaginal examination is required to differentiate these two conditions from each other and from vaginal prolapse, vaginal polyps, fat protrusion from a vaginal tear, vaginal neoplasia, fetal membranes, and uterine prolapse. Prevention of straining through epidural anesthesia is essential because expulsive efforts can cause herniation of other viscera through the urethra (bladder eversion) or through the vaginal tear (bladder prolapse).[100] Epidural anesthesia also facilitates cleaning of the area because straining may result in continual fecal contamination of the perineum and vestibule.

34.41.4.1.1 EVERSION OF THE BLADDER

The mucosal surface of the bladder is exposed. The ureteral openings may be visible on its dorsal aspect, although these may be occluded and difficult to see if the wall of the bladder is edematous.[103] Vaginal palpation reveals that the protruding tissue originates from the urethral orifice. With time, constriction of the everted bladder by the narrow urethra may cause venous congestion, edema, thrombosis, and eventual necrosis.[100] Palpation and ultrasonographic examination are required for detection of herniation of other viscera through the urethral orifice and into the interior of the everted bladder. Strangulation of incarcerated bowel may occur.[101,102] Careful fine-needle aspiration of the interior of the eversion has been used to differentiate eversion from prolapse of the bladder. With bladder eversion, aspiration may yield peritoneal fluid, but laceration of herniated bowel is a concern.[100]

34.41.4.1.2 PROLAPSE OF THE BLADDER

The serosal surface of the bladder is exposed. Careful palpation of the vagina reveals that the bladder protrudes from a full-thickness tear in the floor or lateral wall of the vagina. Other viscera may be present in the vagina as well. Fine-needle aspiration yields urine from the bladder lumen.

34.41.4.2 Treatment and Prognosis

34.41.4.2.1 EVERSION OF THE BLADDER

Manual reduction of the everted bladder may not be possible if it is edematous or if other viscera have herniated into its interior. The dorsal aspect of the urethra may be incised to widen the route through which the bladder is to be replaced.[100,101] Laparotomy is required for assessment of the viability of herniated bowel, and subtotal cystectomy may be performed if extensive bladder trauma or necrosis has occurred.[101] The viability of the involved structures is of primary concern for prognosis. Bladder paralysis and rupture are potential sequelae to ischemic damage that develops during eversion.[100] Cystitis and pyelonephritis may develop as well, and antibiotic therapy is warranted if repair is attempted. Animals with chronic conditions may develop hydroureter, hydronephrosis, and renal failure.[104]

959 960

34.41.4.2.2 PROLAPSE OF THE BLADDER

A flexible catheter may be passed into the urethra to remove urine from the bladder, thereby confirming the diagnosis and facilitating bladder replacement. After catheterization and removal of urine, the bladder can be replaced into the abdominal cavity and the vaginal tear can be sutured. Severe contamination of the peritoneal cavity may render attempts at treatment unjustified. Antibiotic therapy is indicated for surgical candidates.

34.41.4.2.3 PELVIC ENTRAPMENT OF THE BLADDER

DAVID C. Van METRE

In pelvic entrapment of the bladder, the apex and fundus of the bladder are displaced caudodorsally into the pelvic cavity, resulting in impaired urine outflow. In one report the condition was diagnosed in two Holstein cows a few days after parturition had occurred, suggesting a potential role of delivery or postpartum straining in bladder displacement.[105] Entrapment of the bladder in a perineal hernia[106] or within a vaginal prolapse[107] may also occur.

34.41.4.2.3.1 Clinical Findings

Bladder emptying is impaired, and the presence of the bladder in the pelvic inlet induces straining. An affected cow may show tenesmus, pollakiuria, and stranguria. On rectal examination a soft, fluctuant mass may be detected beside the vagina.[105] In calves, radiography has been used to demonstrate the pelvic position of the bladder.[108]

34.41.4.2.3.2

Differential Diagnoses

Differential diagnoses include proctitis, vaginitis, retained placenta, bladder paralysis, cystitis, and perivaginal abscess. Needle aspiration of the bladder per vaginum has been used to make a definitive diagnosis,[105] although the danger of uterine puncture should be considered.[107] Ultrasonographic examination can also be useful for definitive diagnosis.[107] Draining the bladder through catheterization or needle aspiration facilitates replacement of the bladder by manipulation per vaginum. However, laparotomy was necessary in one cow to reset the bladder because of the development of fibrinous adhesions between the bladder and vagina.[105] In cases of bladder entrapment within a vaginal prolapse, complete correction of the prolapse usually restores the bladder to its normal position.[105]

34.41.4.2.4

ENZOOTIC HEMATURIA

DAVID C. Van METRE

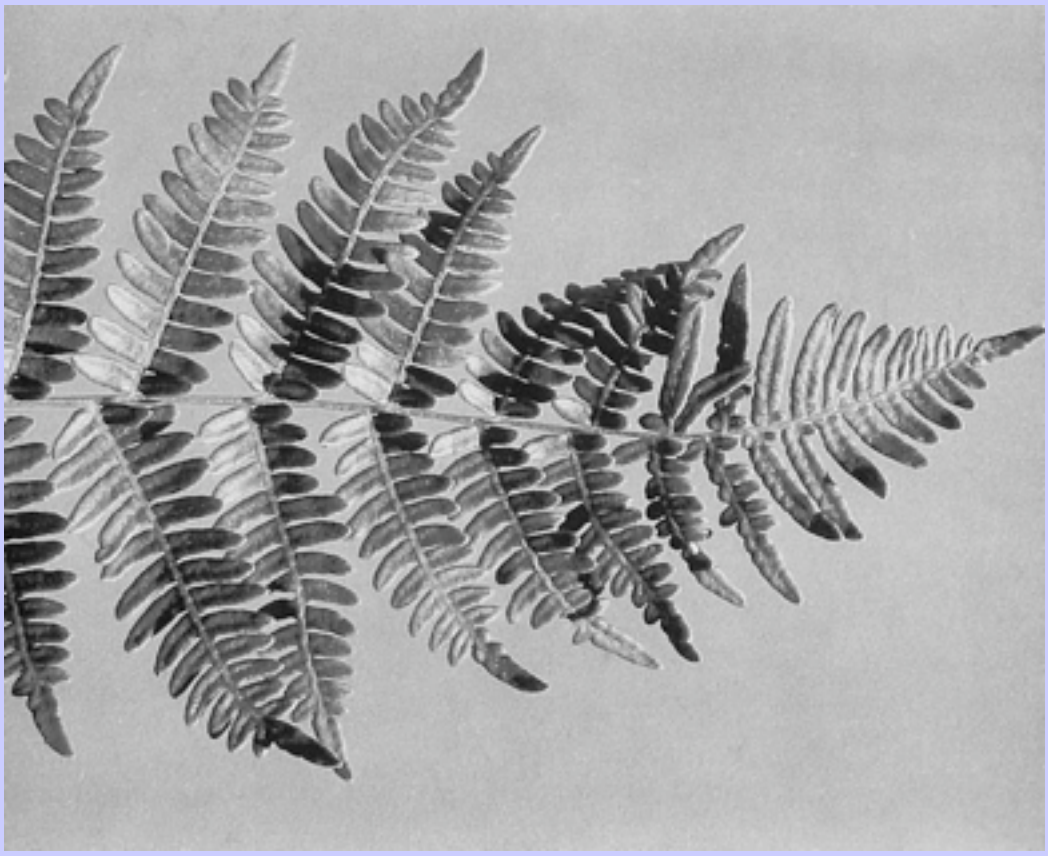
Enzootic hematuria is a disease of chronic or intermittent hematuria in cattle and sheep and is associated with chronic ingestion of bracken fern *(Pteridium aquilinum)*[109–115] (Fig. 34-21). A different fern species, *Cheilanthes sieberi,* may induce this disease in Australian cattle.[109,111] Hemorrhagic cystitis is the initial consequence of exposure to the toxic compound(s) in the plant. With continued ingestion of bracken fern, cattle develop bladder neoplasms of epithelial, mesenchymal, or mixed origin. Bladder infection with bovine papillomavirus type 2 is involved in carcinogenesis.

34.41.4.2.4.1

Clinical Findings

In most cases, several animals are affected in a group that is grazing a particular pasture or being fed a particular type or cutting of hay. Protracted, possibly intermittent, hematuria is the first clinical sign detected in most animals.[109] Blood clots may be voided on occasion. Chronic blood loss eventually results in tachycardia, tachypnea, exercise intolerance, pale mucous membranes, and a decline in productivity and body condition. Bladder wall thickening and bladder tumors may be palpated per rectum. Proliferative changes or overt neoplasia of the bladder may cause dysuria, pollakiuria, and rarely, obstruction of the bladder trigone. Occasionally, blood clots may cause urethral obstruction. Depending on the magnitude and duration of bracken fern ingestion, hematuria may last for months to years before severe debilitation or death occurs. Ultrasonographic examination of the urinary bladder of affected animals may reveal bladder thickening and an irregularly shaped bladder wall. In an Indian study, affected cattle showed a bladder wall thickness of 4 to 5 mm (normal, 1 to 2 mm).[110]

Fig. 34-21 Bracken fern *(Pteridium aquilinum)*.



The syndrome of enzootic hematuria is quite different from acute bracken poisoning, which occurs after ingestion of large quantities of bracken fern (approximating the animal's body weight), usually over 1 to 3 months.[111,112] Acute bracken poisoning manifests as an acute coagulopathy or fulminant septicemic crisis associated with severe bone marrow suppression. Clinical signs include fever, profound weakness, epistaxis, hyphema, dysentery, and petechial hemorrhages of the mucosal surfaces and sclera.[111] Acute bracken poisoning is further described in Chapter 54.

34.41.4.2.4.2

Clinical Pathology

Severe anemia is often seen on hematologic examination of cattle and sheep with enzootic hematuria. Evidence of a regenerative response may not be present if bone marrow suppression is severe. The platelet, segmented neutrophil, and lymphocyte counts may be reduced.[111–113] Urinalysis reveals hematuria, proteinuria, and variable pyuria.[109]

34.41.4.2.4.3

Differential Diagnosis

Examination of serum for evidence of hemolysis and analysis of sediment from a freshly voided urine sample for intact red blood cells allow for differentiation of hematuria from the hemoglobinuria found in hemolytic diseases. Icterus, also characteristic of ruminant hemolytic disorders, is not found in cases of enzootic hematuria. Hematuria may be evident in urinary tract infection, but pyuria and bacteriuria are marked, and anemia, if present, is usually mild. Simultaneous involvement of several animals is uncommon with urinary tract infection but common in enzootic hematuria. Hematuria may be evident in cattle affected by malignant catarrhal fever (MCF). Protracted, severe hematuria is rare in cases of urolithiasis, and anemia is also not expected. Without necropsy, a diagnosis of enzootic hematuria requires documentation of access to bracken fern in animals with characteristic clinical signs and laboratory data.

960

961

34.41.4.2.4.4

Epidemiology

Enzootic hematuria has a wide geographic distribution, with cases reported in North and South America, the United Kingdom, Australia, and several European countries.[109] Bracken fern is found in all areas of the United States except the Great Plains, with most livestock poisonings occurring in the Pacific Northwest and upper Midwest.[112] The plant grows best in well-drained, fertile soils and is often localized in open areas of forests.[114] Sheep and cattle are poisoned by grazing the plant or consuming contaminated hay.[114]

Enzootic hematuria is primarily seen in adult sheep and cattle. In field cases, cattle grazing infested pastures develop hematuria by 2 to 3 years of age.[109,115] Feeding adult cattle 1 to 2 kg bracken fern/head/day led to hematuria within 10 to 15 months in one trial.[109] Papillomas of the bladder occur as early as 1 year after bracken feeding begins, with invasive carcinomas arising 2 to 6 years later.[109,115]

34.41.4.2.4.5

Pathophysiology

All parts of the plant are toxic to sheep and cattle.[111,112] Several compounds in bracken fern possess irritant, mutagenic, immunosuppressive, or carcinogenic activities.[109,113] These include ptaquiloside (aquilide A), quercetin, and a-ecdysone.[116–119] The carcinogenic principles are present in the milk of cows grazing bracken fern.[120,121] Bracken fern compounds may cause recrudescence of latent bovine papillomavirus 2 (BPV-2) infections through immunosuppression. Bladder infection with BPV-2 follows, and mutagenic compounds in bracken fern interact with BPV-2 in the bladder to induce local neoplasia.[109,113,116] Growth of the resultant neoplastic tissue may be enhanced by further exposure to mutagenic bracken compounds.[109,113,116] Similarly, BPV-4 and mutagens from bracken fern may act in synergy to induce neoplasia of the mucosa of the upper GI tract.[116,118,119]

In multiple species, cyclooxygenase 2 (COX-2) is overexpressed in epithelial neoplasms, including those of the urinary bladder origin. Certain types of tumors of urinary epithelium may coexpress COX-1 and COX-2. Bladder carcinomas from cows with enzootic hematuria have been shown to express both COX-1 and COX-2 at a high level relative to normal controls, when evaluated by immunohistochemical

methods.[122] The efficacy of COX-2 inhibitor drugs on cancer prevention or treatment in cattle at risk for bladder tumors remains to be investigated.

Immunosuppression results from reduction in circulating neutrophil and lymphocyte counts. Neutropenia appears to be a reversible phenomenon that results from bone marrow suppression. Neutrophil counts may normalize within 1 to 2 weeks of cessation of bracken feeding. Lymphopenia persists during periods of low-level ingestion.[113]

34.41.4.2.4.6

Necropsy Findings

Tissue pallor from anemia is often appreciated. The bladder wall is thickened and the mucosa hemorrhagic and ulcerated. Microscopic examination of the bladder wall reveals capillary engorgement, intramural hemorrhage, and metaplasia of the bladder epithelium.[111] Several types of bladder tumors and mixed-origin neoplasms may be present. Metastasis of epithelial neoplasms to the regional lymph nodes or other organs can occur.[123] Pharyngeal, esophageal, or ruminal papillomas may be found as well, and carcinomas may develop in these same locations in cattle exposed to bracken fern over several years.[115]

34.41.4.2.4.7

Treatment and Prevention

Treatment of enzootic hematuria is limited to reduction or elimination of bracken fern in the diet. Wooded areas that support growth of bracken fern can be fenced off, and forage improvement may help to limit incorporation of the plant into hay. If such measures are not feasible, a program of early culling may help to avoid low productivity from anemia and neoplasia. Hematuria will cease if bracken feeding is discontinued before the onset of tumor formation.

34.41.4.2.5

URINARY TRACT INFECTION

David C. VAN Metre

Cystitis, ureteritis, and pyelonephritis in ruminants most often result from ascending urinary tract infection (UTI) with *Corynebacterium renale* or *Escherichia coli*.[124] Less common causative organisms include various coliform species[125] and other members of the *C. renale* group.[126] Renal infection via the hematogenous route (suppurative embolic nephritis) is much less common but may result from bacteremia with such agents as *Salmonella* species, *Actinomyces pyogenes,* or in small ruminants, *Corynebacterium pseudotuberculosis*.[127]

34.41.4.2.5.1

Clinical Signs

Cystitis in cattle is typified by dysuria and pollakiuria, with or without gross hematuria and pyuria. During urination the flow rate is often decreased. An affected cow may tread or swish the tail and retain an arched stance after voiding has ceased. Blood, purulent debris, or crystalline material may occasionally be found on the hairs of the ventral commissure of the vulva. Rectal palpation may reveal a thickened, painful bladder. If UTI is limited to the bladder, an affected cow usually does not show generalized signs of infectious disease (e.g., fever, anorexia, depression).[124]

In contrast, cattle with acute pyelonephritis often have a history of an abrupt reduction in feed intake and milk production. Fever, depression, ruminal stasis, scleral injection, and occasional episodes of mild colic accompany the signs of cystitis previously described.[124] With bilateral or left-sided pyelonephritis, renal enlargement, pain, and a loss of normal lobulation of the left kidney may be evident on rectal examination. Transabdominal ultrasonographic examination is useful for evaluation of the right kidney, because the right kidney usually cannot be reached during rectal examination unless it is greatly enlarged.[124] In an adult cow, ultrasound evaluation of the right kidney can be performed using a 3.5-MHz transducer at the twelfth intercostal space. This transducer can also be used to view the left kidney at the dorsocranial aspect of the right paralumbar fossa.[128] Alternatively, the left kidney can be imaged transrectally with a linear-array transducer. Dilation of renal calyces; echogenic, flocculent material within the renal pelvis; abnormal renal shape; and renal enlargement are ultrasonographic findings suggestive of pyelonephritis. Vaginal palpation is usually necessary to detect ureteritis[124]; the ureters may be enlarged and painful when palpated through the vaginal wall.

The clinical signs of chronic pyelonephritis are relatively vague and inconsistent.[124] Weight loss or poor growth rate, anorexia, and reduced milk production are common presenting complaints. Posture and behavior during urination may be normal, although affected calves have been noted to dribble urine, thereby developing phosphatic calculi adherent to the vulvar hairs and urine scald of the perineum and hindlegs. Ulcerative vulvovaginitis may be present as well.[129] Polyuria without gross urine abnormalities 961
may be found in some cases. Diarrhea and pale mucous membranes may also be seen during physical 962
examination. Rectal and vaginal examination findings for chronic pyelonephritis are similar to those of the acute form, although the involved structures may not be painful or enlarged when palpated.

Urinalysis with chemical reagent strips appears to be a sensitive ancillary test for both acute and chronic pyelonephritis. In a study of 15 cases of bovine pyelonephritis, clinical signs suggestive of urinary tract disease were found in only three cows. However, evidence of hematuria or proteinuria was found through routine reagent strip urinalysis in all 15 cases.[124] Further examination and testing of the urinary tract confirmed a diagnosis of pyelonephritis.

34.41.4.2.5.2

Differential Diagnosis

Mild colic may result from a variety of GI disorders, but urinalysis findings are normal in these conditions. Enzootic hematuria usually affects multiple animals in a particular locale, and access to bracken fern is usually demonstrable. Although dysuria and hematuria may be evident in enzootic hematuria, anemia is profound, whereas pyuria and bacteriuria are mild or nonexistent. Urolithiasis may induce colic, dysuria, and hematuria. However, urolithiasis is almost exclusively a disease of male ruminants, and UTI is more common in females. Bladder distention is a common finding in urolithiasis but rarely occurs in UTI. Other conditions that may cause dysuria include vaginitis, vulvar trauma, perivaginal abscesses, and pelvic entrapment of the bladder. Careful assessment of the neurologic system is warranted in cases of UTI to determine if the underlying cause is bladder paresis or incomplete voiding.

34.41.4.2.5.3

Clinical Pathology

Neutrophilic leukocytosis and hyperfibrinogenemia are evident on hematologic evaluation of cattle with pyelonephritis. Hyperglobulinemia may develop if the infection is established for several days. Severe, protracted proteinuria may cause hypoalbuminemia, and the resultant low plasma oncotic pressure may contribute to the development of diarrhea in occasional cases. In chronic pyelonephritis, anemia may result from reduced erythropoietin production, chronic inflammatory disease, and blood loss through the urine.[124]

If azotemia is found on serum chemistry analysis, the clinician must consider renal and prerenal causes before formulation of a prognosis. Pyelonephritis with azotemia and isosthenuria would indicate bilateral renal involvement, lowering the chances for successful treatment.[124]

Urinalysis is required for definitive diagnosis of UTI, but careful collection technique is important for valid conclusions to be made. Concurrent metritis, vaginitis, or posthitis may result in contamination of urine with blood, bacteria, and inflammatory cells, particularly if the rate of voiding is slow. A midstream or end-stream catch is likely to provide the most accurate culture results.[130] Tentative identification of the organism may be obtained through Gram stain of the urine.

Urinary tract infection consistently produces hematuria, proteinuria, and bacteriuria on urinalysis. Quantitative culture of a urine sample allows for confirmation of the diagnosis and identification of the causative organism. Although not present in all cases, leukocyte casts provide definitive evidence of pyelonephritis.[131]

34.41.4.2.5.4

Pathophysiology

Factors involved in ascending UTI include the dose and virulence of the bacterial challenge, the presence of urogenital trauma (e.g., from calving injuries) or abnormal vulvar conformation, obstetric manipulation, bladder catheterization, and urine retention (as occurs with bladder paralysis or urethral obstruction). After cystitis is established, alterations in the contractility and thickness of the bladder wall may promote vesicoureteral reflux, spreading infection into one or both ureters.[132] Hemorrhage, fibrin deposition, and epithelial necrosis may result in intermittent ureteral or renal obstruction, which may be responsible for the episodic signs of colic occasionally seen in affected cows. Once pyelonephritis is established, necrosis of papillary and tubular epithelium leads to accumulation of necrotic debris in the renal pelvis, loss of functional nephron mass, abscess formation, fibrosis, and distortion of renal shape. Renal calculi, particularly struvite uroliths, may occasionally develop in cases of pyelonephritis. Crystal deposition on necrotic debris and the high local pH caused by bacterial urease activity may contribute to calculogenesis.

Corynebacterium renale is a large, pleomorphic, club-shaped bacillus that is aerobic, ureolytic, nonmotile, and gram positive.[126] Pyelonephritis caused by *C. renale* has been reported in a sheep[132] and induced experimentally in goats.[133]*C. renale* is adapted to and maintained in the bovine and ovine urinary tract and is unlikely to be maintained in the external environment for prolonged periods.[126] Subclinical carriers and diseased animals transmit the organism through direct vulvar contact or by splashing urine droplets onto the vulvas of susceptible cows. Iatrogenic transmission through

contaminated obstetric instruments or urinary catheters is also possible. Venereal transmission of *C. cystitidis*[126] and *C. renale*[134,135] from infected bulls may also occur.

Adherence of *C. renale* to urinary tract epithelium appears to be mediated by pili[136] in a pH-dependent manner.[137] Adherence is enhanced under alkaline conditions and inhibited by acidic conditions. This may explain the clinical improvements reported in infected cattle fed salts that promote urinary acidification.[134] Through ureolysis and ammonia production, the organism maintains urine alkalinity, thereby facilitating colonization of the epithelial surface. A serum antibody response develops after renal infection is established, but this response is rarely curative[124] and does not appear to impart resistance to reinfection with *C. renale*.[138]

Ruminant UTI is also frequently caused by *Escherichia coli,* a ubiquitous, gram-negative coliform bacterium.[124] The serotype(s) and virulence factors of *E. coli* involved in bovine pyelonephritis have not been identified. Clinical evidence suggests that UTI results from fecal contamination of the urogenital tract or loss of normal urinary tract defenses.

Congenital defects such as ectopic ureter occasionally result in UTI, presumably from ascending infection of an abnormally positioned ureter. Impairment of bladder emptying, as might occur with bladder adhesions, urachal remnant infection, or diseases of the spinal cord, may promote ascending UTI. Urethral trauma caused by urolithiasis, breeding injury, urogenital papillomas, or catheterization of the urethra may also be conducive to infection.

34.41.4.2.5.5

Epidemiology

An Israeli study found that the prevalence of pyelonephritis on a per-farm basis varied between 0.3% and 2.7%.[139] UTI is much more common in female ruminants than in males because of the relatively short urethral length in females[140] and the potential for urinary tract contamination and trauma during parturition. Seventy-three percent of pyelonephritis cases developed within the first 90 days after calving, suggesting that the postpartum period is a critical time for initiation of UTI.[139] Another study identified reproductive tract abnormalities such as pneumovagina, metritis, and poor perineal conformation in 7 of 15 cows with pyelonephritis.[124]

962

963

In the past, *C. renale* has been regarded as the most common causative organism for bovine pyelonephritis[125]; however, in recent studies from Israel, *E. coli* has been the most frequent cause.[129,141] Once *C. renale* infection exists in a herd, the number of subclinically infected cows increases over time, and the infection becomes difficult to eradicate.[126] Through increased frequency of contact, overcrowded cattle may experience more rapid transmission of infection.

34.41.4.2.5.6

Necropsy Findings

Hemorrhage, ulceration, and fibrin deposition are evident on the epithelium of the bladder and urethra. With chronic infection, polypoid growths may develop in the bladder mucosa; these masses grossly resemble tumors and must be definitively identified by histopathologic examination.[125] One or both ureters may be enlarged, with purulent debris occasionally occluding the ureteral lumen. Pyelonephritis cases may show gross renal enlargement in acute to subacute cases (Fig. 34-22). On sagittal sectioning of

the kidney, viscous, gray, odorless exudate is found within the renal pelvis and extending into the medulla and cortex.[126] A Gram stain of the exudate is useful for differentiation of *C. renale* from *E. coli* infection. Renal abscesses, with gross distortion of renal size and shape, may be seen in cases of chronic pyelonephritis.

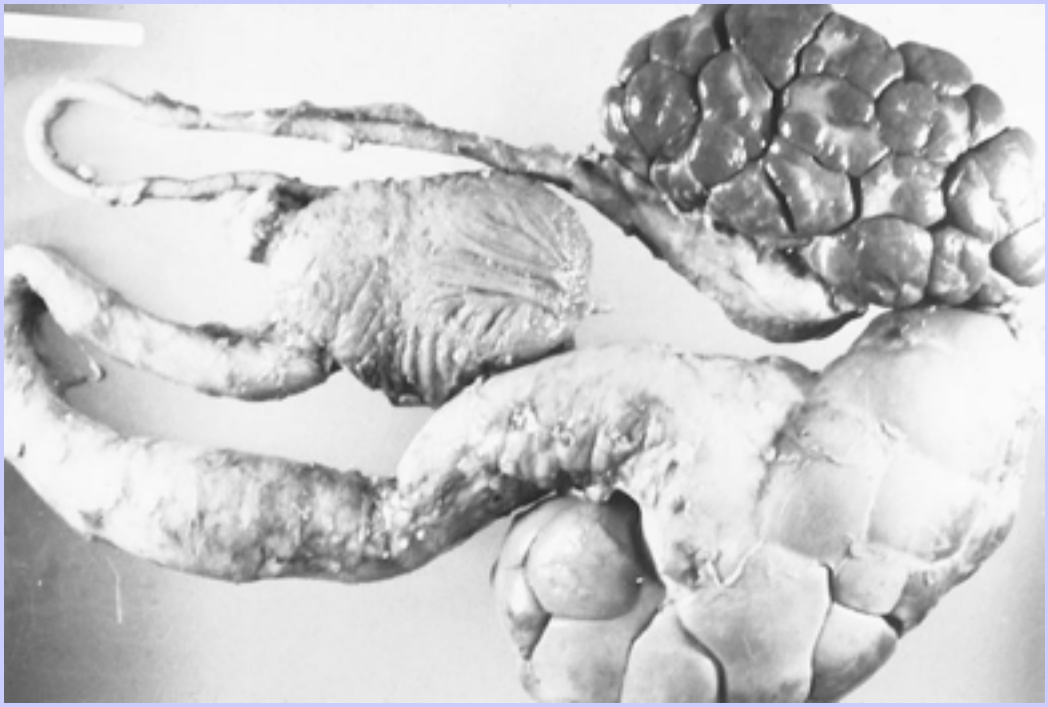
34.41.4.2.5.7

Treatment and Prognosis

Aggressive antibiotic therapy is essential for successful treatment of UTI. Penicillin is the treatment of choice for *C. renale* infection; recommended dosage regimen includes procaine penicillin G (22,000 to 44,000 IU/kg IM twice daily) or ampicillin trihydrate (11 mg/kg IM twice daily).[124] For valuable animals, higher serum and urinary concentrations of penicillin may be achieved with IV administration of sodium or potassium penicillin (22,000 to 44,000 IU/kg every 6 hours) or sodium ampicillin (10 to 50 mg/kg every 8 hours). Treatment should be continued for a minimum of 3 weeks. Subcutaneous injection of antimicrobial drugs may be necessary to limit muscle pain and swelling during the course of treatment. Urinalysis and urine culture should be repeated 1 week after treatment is discontinued to ensure complete resolution. After prolonged therapy with these extralabel dosages of antibiotics, residue withdrawal times for meat and milk must be extended appropriately. In addition, induction of diuresis through oral or parenteral fluid therapy may aid in removing necrotic debris and bacteria from the lumen of the urinary tract.

Urinary tract infection with *E. coli* or other coliforms may also be successfully treated with high doses of penicillin or ampicillin.[124] Achieving high urinary concentrations of these antibiotics may render them effective against many coliforms, even those that show in vitro resistance to the expected serum concentrations of the antibiotic.[124] Repeated assessment of appetite, attitude, rectal temperature, and reagent strip urinalysis is recommended for monitoring cows with coliform UTI that are receiving penicillin or ampicillin therapy. If these parameters do not improve after 96 hours of treatment, another antibiotic should be chosen.[124] Gentamicin (2.2 mg/kg IM twice daily) has been used to successfully treat refractory coliform UTI in a cow, but the nephrotoxicity of the drug and the current prolonged slaughter withdrawal period are important considerations.[124] Trimethoprim-sulfadiazine (15 mg/kg IV once daily)[125] and ceftiofur (3 mg/kg IV twice daily)[142] have also been used with success.

Fig. 34-22 Postmortem specimen of unilateral pyelonephritis and ureteritis in a cow. The affected kidney and ureter are greatly enlarged.



The prognosis for UTI in ruminants depends on the duration of infection, the extent of UTI (cystitis alone vs. unilateral or bilateral ureteritis and pyelonephritis), and the remaining renal function. The chances for successful treatment are improved if treatment is initiated early in the course of infection. In recent reports the combined case fatality and cull rate for pyelonephritis in dairy cattle varied between 18%[124] and 33%[139] for treated cases; however, antibiotic dose and duration varied greatly between these two studies. Cows with pyelonephritis and marked azotemia (BUN >100 mg/dL) were found to be at much greater risk for culling (odds ratio = 60) than nonazotemic cows with pyelonephritis.[139]

34.41.4.2.5.8

Prevention and Control

Isolation of animals infected with *C. renale* is recommended to limit spread of the organism, and disinfection of heavily contaminated areas is advised. Aseptic technique during urogenital procedures and disinfection of obstetric and surgical equipment will limit iatrogenic transmission. In herds using natural service, venereal transmission by subclinically infected bulls may be difficult to control over the long term. An artificial insemination or mass treatment program may be required to prevent further losses from UTI.

34.41.4.2.6

AMYLOIDOSIS

DAVID C. Van METRE

Amyloidosis in cattle is caused by deposition of insoluble protein fibrils in the kidney, GI tract, liver, and adrenal glands. Renal amyloidosis in cattle is characterized as a sporadic, chronic wasting disease. Amyloid deposition in the kidney disrupts the normal glomerular structure, resulting in a protein-losing nephropathy.

34.41.4.2.6.1

Clinical Signs

The most common clinical signs of amyloidosis include chronic diarrhea, weight loss, and poor productivity in mature animals.[143,144] Generalized or ventral edema may be present as a result of hypoproteinemia. Alterations in appetite and attitude may be present, although this may be caused by concurrent disease. Enlargement of the left kidney may be palpated during rectal examination. The enlarged kidneys generally are not painful and maintain normal lobular patterns. Urine may develops stable foam after hitting the ground or being collected and shaken in a container, a result of high urine protein concentration.

34.41.4.2.6.2

Clinical Pathology

Cattle with renal amyloidosis consistently develop marked proteinuria and hypolbuminemia.[143] Serum creatinine and BUN levels may be elevated if renal damage is advanced. In cases of chronic, active inflammatory disease, hyperfibrinogenemia and hyperglobulinemia may occur.[143,144] Polarized light microscopy and electron microscopy have been used to examine urine sediment for the presence of amyloid protein in urine.[145]

963

964

34.41.4.2.6.3

Differential Diagnosis

Amyloidosis must be differentiated from other diseases causing chronic diarrhea, hypoproteinemia, weight loss, and poor productivity. Diseases to consider include Johne's disease, copper deficiency, salmonellosis, bovine viral diarrhea, GI parasitism, and glomerulonephritis. Other than amyloidosis, glomerulonephritis is the only other differential diagnosis routinely displaying prolonged proteinuria. Renal biopsy can be performed to differentiate glomerulonephritis from amyloidosis in the live animal.

34.41.4.2.6.4

Pathophysiology

Amyloidosis of cattle is classified as the reactive (AA) type,[146,147] which is frequently associated with chronic inflammatory disease in domestic animals and humans.[148] Concurrent inflammatory disease, such as traumatic reticuloperitonitis, pneumonia, mastitis, and metritis, have been found in some, but not all, cattle with amyloidosis.[143,144] Serum amyloid A protein (SAA) is synthesized in the liver and is a precursor of amyloid A (AA) fibril in tissues.[149] SAA concentrations increase dramatically in disorders such as trauma, neoplasia, and inflammatory disease. An elevation in SAA is apparently required for an animal to develop active amyloidosis.[148] Elevations in SAA as a result of abnormal catabolism by the reticuloendothelial system may also increase AA fibril formation.[148,150] AA fibrils are resistant to

proteolysis, allowing for their accumulation in tissues over time.[146] Accumulation of amyloid in the glomerulus alters glomerular filtration. A resultant hypoalbuminemia develops, which in turn decreases intravascular oncotic pressure. Diarrhea develops as a result of edema or amyloid deposition in the GI tract.[144] The protein-losing nephropathy and diarrhea result in weight loss. Glomerular filtration rate will be reduced if the glomeruli are obliterated by amyloid deposition. Renal or pulmonary thrombosis may develop as a result of the loss of low—molecular-weight anticoagulants through the compromised kidney.[151]

34.41.4.2.6.5

Necropsy Findings

Renal enlargement with yellow-tan to white discoloration is frequently present. A waxy quality of the renal parenchyma may be appreciated on cut surface of the kidney.[143] Generalized edema resulting from hypoalbuminemia may be present. Some animals will have renal or pulmonary thrombosis.[144] Other inflammatory lesions may be found in other sites. Histologic examination of the kidney may reveal amyloid deposition in the glomerulus, interstitium, and tubule lumen. Immunohistochemical tests using antihuman AA monoclonal antibody can be used for specific demonstration of amyloid in bovine kidney specimens.[151]

34.41.4.2.6.6

Prognosis

Because the lesions of amyloidosis are irreversible, the prognosis for affected cattle is poor. The resilient nature of the amyloid protein results in its persistence in tissues, even if the underlying cause of inflammatory disease is treated successfully. Specific treatment for amyloidosis has not been reported in cattle.

34.41.4.2.7

GLOMERULONEPHRITIS

DAVID C. Van METRE

Glomerulonephritis (GN) is a rare clinical disorder of ruminants that may result from deposition of antigen-antibody complexes in the glomerular basement membrane or from binding of antibody to intrinsic or foreign antigens in the glomerulus. Glomerular injury occurs subsequent to targeting of glomerular tissues by the immune system. Nonimmune mechanisms may be involved in certain forms of the disease.

34.41.4.2.7.1

Clinical Signs

Cattle with GN may have a history of weight loss, poor productivity, and chronic diarrhea.[152,153] Lethargy and generalized edema may be detected on physical examination. Rectal palpation may reveal a mildly enlarged but nonpainful left kidney.[153] GN may be clinically occult in cattle persistently infected with bovine viral diarrhea (BVD) virus[154] and in cattle with fascioliasis.[155] GN has been associated with pregnancy toxemia in ewes; affected animals tend to show clinical signs typical of pregnancy toxemia[156] (see Chapter 33).

Mesangiocapillary GN has been described in Finnish Landrace lambs of specific lineage in Scotland and Canada.[157] The disease is heritable, but the exact mode of inheritance remains unknown. Clinical signs of

this disease begin within hours after birth to 3 months of age. Affected lambs may be dull, ataxic, and appear blind. Fine muscle tremors, colic, and convulsions may also be seen.

34.41.4.2.7.2

Differential Diagnosis

The differential diagnosis for cattle with GN is similar to that for amyloidosis (see preceding section).

34.41.4.2.7.3

Clinical Pathology

Heavy proteinuria, mild anemia, and hypoalbuminemia have been reported in cattle with GN.[152,153] Granular casts, red blood cells, and leukocytes were found in the urine sediment of one affected cow.[152] Azotemia, proteinuria, and ketonuria are found in ewes with GN associated with pregnancy toxemia. Mesangiocapillary GN in Finnish Landrace lambs is characterized by uremia, hypoalbuminemia, proteinuria, hypocalcemia, and hyperphosphatemia.[157]

34.41.4.2.7.4

Pathophysiology

In humans, GN may result from a variety of infectious, toxic, or autoimmune disorders, all of which induce eventual immunologic injury to the glomerulus.[152,158] Antibodies may be directed against host or foreign antigens located in the vascular endothelium, mesangial cells, or basement membrane. In addition, circulating immune complexes may deposit in the glomerulus. The ultimate consequences of antigen-antibody interaction in the glomerulus are activation of complement and chemotaxis of leukocytes, both of which result in direct glomerular injury and increased glomerular permeability.[158]

Filtration of plasma albumin through the damaged glomerulus results in chronic albuminuria, eventually leading to reduced plasma oncotic pressure and generalized edema. Passage of antithrombin III through the damaged glomerulus and into the urine may result in a hypercoagulable state.[159]

Immunohistochemical data suggest involvement of immune-mediated mechanisms for spontaneous GN in cattle[152,153] and sheep,[157] GN associated with persistent BVD infection and fascioliasis in cattle,[154,155] and mesangiocapillary GN of Finnish Landrace lambs.[157] In the last condition a heritable deficiency of the third component of complement has been documented, but the role of this deficiency in GN remains unclear.[156] Glomerulonephritis may also be an incidental histologic finding in animals with acute septic disease.[157]

The clinical and histopathologic characteristics of GN of pregnancy toxemia in ewes resemble those of the preeclampsia syndrome of women.[156] Enlarged glomeruli with reduced blood content in glomerular capillaries are found throughout the renal cortex of affected ewes. The renal lesion in preeclampsic women may result from endothelial injury during disseminated intravascular coagulation (DIC) or an excessive glomerular vasomotor response to angiotensin.[160] The lesion can be reversible in women, but the consequences of this condition in ewes have not been described.

964
965

34.41.4.2.7.5

Treatment and Prognosis

Treatment of GN in ruminants has not been described. Because most cases of GN are advanced at diagnosis, the prognosis is poor. Mesangiocapillary GN in Finnish Landrace sheep is not invariably lethal, and some affected lambs may survive until adulthood.[156]

34.41.4.2.8

HEMOLYTIC UREMIC SYNDROME

DAVID G. RENTER

Hemolytic uremic syndrome (HUS) is classified within the group of thrombotic microangiopathy syndromes.[161] HUS is a set of symptoms characterized clinically by acquired, nonimmune hemolytic anemia, thrombocytopenia, and acute renal failure (ARF).[162] Histologically, HUS is characterized by renal thrombotic microangiopathy.[163] HUS is the most common cause of ARF in young children and infants, with prodromal diarrhea occurring in approximately 90% of cases.[164] Evidence indicates that almost all the postdiarrheal human cases of HUS are caused by enterohemorrhagic (EHEC) or verotoxigenic *Escherichia coli* infections, and that the majority of the cases in the United States are caused by the EHEC serotype O157:H7.[164] Although three horses[165,166] and a heifer[167] have been reported with clinical syndromes similar to HUS, an etiologic agent was not identified in any of these four animals.

34.41.4.2.8.1

Clinical Findings

Horses with clinical signs indicative of HUS have exhibited fever, diarrhea, hematuria, hemoglobinuria, profound azotemia, oliguria, and ventral edema.[165,166] Hematologic findings included leukocytosis, anemia, and evidence of hemolysis.[165,166] The blood smear of one horse revealed the presence of poikilocytes and schistocytes.[166] All three horses were euthanized after unsuccessful treatment of anuria and azotemia with fluid therapy and diuretics. The reported case in a heifer was fatal postparturient HUS demonstrated by severe progressive anuric renal failure, acute hemolytic anemia, and consumptive thrombocytopenia.[167]

In humans, HUS presents as pallor, oligoanuria, edema, seizures (rarely), or generalized hemorrhagic diathesis. In prodromal human cases, this syndrome develops on average 1 week after onset of diarrhea.[162] The classical clinical syndrome of HUS in people includes ARF, hemolysis, thrombocytopenia, and manifestations of DIC.[163] For treatment of HUS in humans, evidence is insufficient to support use of specific therapies, and some treatments, such as certain antibiotics and motility-modifying agents, may be detrimental.[162] Supportive therapy, including fluid/plasma therapy and dialysis, can be of paramount importance.

34.41.4.2.8.2

Pathophysiology and Necropsy Findings

In humans, HUS is the most common life-threatening complication of hemorrhagic colitis (HC) from EHEC infection. The EHEC strains produce the exotoxins Shiga toxin 1 (Stx1) and Shiga toxin 2 (Stx2), also referred to as verotoxin 1 and verotoxin 2.[168] Although *E. coli* O157:H7 is the most widely

publicized, as many as 100 different serotypes of *E. coli* (as well as *Shigella* and other Enterobacteriaceae) can carry the genes for Stx1 or Stx2 and are capable of causing disease.[161]

The EHEC organisms, including serotype O157:H7, are noninvasive but attach to the intestinal mucosa and produce characteristic histologic attaching and effacing lesions. The Shiga toxins (Stxs) released from the bacteria are believed to translocate across the mucosa, where they access the systemic circulation. The Stxs bind to specific glycolipid receptors on the surface of vascular endothelial cells, are internalized by endocytosis, and induce cell death through inhibition of protein synthesis.[161] Activation of the coagulation cascade after exposure of subendothelial collagen may result in thrombosis of small vessels in the kidney and other organs. Oliguric or anuric ARF can result from fibrin/platelet thrombi in renal vessels and glomeruli, fibrinoid necrosis of vessel walls, congestion of glomeruli, and tubular ischemia. Because the coagulation events may be localized to certain organs, the results of laboratory tests of coagulation (e.g., PT, PTT) are not consistently abnormal.[169]

Cattle feces are considered to be the major source of EHEC; however, these bacteria have been isolated from the feces of many other asymptomatic species, including humans. EHEC organisms do not generally cause illness in cattle, although they do colonize the bowel. Fecal contamination of ground beef, other food sources, and water is thought to be the primary mode of transmission of the organisms. However, the small infectious dose makes person-to-person transmission a significant problem, especially in day care, nursing home, and outbreak situations.[161]

In the four large animals reported with HUS, the inciting cause was uncertain, and the isolation of EHEC or other Stx-producing organisms was not attempted.[165–167] The heifer had a necrotizing endometritis, but during postmortem examination of the three horses, no focus of infection was identified. Renomegaly, renal infarcts, and scattered petechial and ecchymotic hemorrhages within the renal parenchyma were apparent on gross necropsy. Acute tubular necrosis and fibrin thrombi within the glomerular capillaries were evident on histologic examination.

Although the etiology was not determined, the clinical signs and pathologic lesions reported in the four large animal cases are compatible with a diagnosis of HUS. Based on these reports, the pathogenesis of HUS in large animal animals shares some features of the disease in humans.

34.41.4.2.9

TUBULAR NECROSIS

DAVID C. Van METRE

Tubular necrosis (TN), or *tubular nephrosis,* is the disease condition that results from a variety of toxic, infectious, or hemodynamic insults to the kidneys. Compounds identified as nephrotoxins for ruminants are listed in Box 34-2. Hemodynamic causes of TN include diseases that reduce renal perfusion (blood loss, endotoxic shock) or that occlude the renal vasculature (DIC, renal vein thrombosis). Bilateral bacterial infection of the kidneys may result in ARF or chronic renal failure (CRF) as a result of destruction of nephrons by bacterial toxins and the host inflammatory response. Renal infection may be established by ascending UTI or by hematogenous infection of the kidneys. Depending on the nature and duration of the primary insult, widespread dysfunction or necrosis of tubular epithelial cells may produce reversible renal injury, ARF, or CRF.

34.41.4.2.9.1

Clinical Signs

The clinical signs of ARF in ruminants are nonspecific and usually are not indicative of overt urinary tract dysfunction. Depending on the inciting cause, anuria, oliguria, or polyuria may exist. Cattle with ARF frequently are presented for evaluation of poor appetite, diarrhea, or epistaxis.[170] Depression, nasal discharge, ileus, melena, and mild free-gas bloat may also be present. If a concurrent septic condition exists, fever, tachycardia, and scleral injection may be present. The saliva may have a strong ammonia smell. Muscular weakness, even recumbency, may result from the acid-base and electrolyte imbalances and intravascular volume depletion that occur with severe acute TN. Rectal palpation findings are usually unremarkable, although renal enlargement and perirenal edema may be found in occasional cases. Table 34-2 lists clinical criteria that may facilitate diagnosis of TN caused by nephrotoxins. If untreated, CRF may ensue, usually producing weight loss in addition to the signs just listed. In such cases a reduction in size of the left kidney may be appreciated on rectal palpation of affected cattle.

Renal (uremic) *encephalopathy* is a syndrome of brain dysfunction associated with renal disease. It is characterized by signs of intracranial disease, such as altered behavior or sensorium, weakness, motor dysfunction, and convulsions, which may resolve on restoration of normal renal function or improvement of clinical parameters of renal disease. The pathogenesis of renal encephalopathy is complex and incompletely understood; neurologic function appears to be impaired by alterations in the extracellular fluid content of acids, phosphorus, amino acids, or certain hormones. Alteration in neurotransmitter balance or release within the central nervous system (CNS) may also be involved. Renal encephalopathy appears to be a rare complication of renal failure in ruminants, as reported in two cows and a goat.[171–173]

34.41.4.2.9.2

Differential Diagnosis

Formulation of a differential diagnosis for a ruminant with TN may be difficult because of the nonspecific nature of the clinical signs and the variety of primary disease conditions that may predispose cattle to secondary TN. Coagulopathies and pulmonary abscesses are common causes of epistaxis in ruminants. The differential diagnoses for diarrhea are listed in Chapter 7. Female ruminants with advanced pregnancy toxemia may be depressed, azotemic, inappetent, and recumbent. Recumbent cattle should be evaluated for musculoskeletal injury, mastitis, metritis, peritonitis, spinal cord disease, and metabolic diseases. Cattle with TN are frequently misdiagnosed with milk fever because a temporary improvement in muscular strength may be seen in cattle with TN after treatment with calcium salts.

34.41.4.2.9.3

Clinical Pathology

Elevation in BUN and creatinine levels occurs with clinical TN, and the azotemia is confirmed to be of renal origin by detection of isosthenuria on measurement of urine specific gravity. Proteinuria, hematuria, and granular casts may be found on urinalysis. Hypochloremia and metabolic alkalosis, resulting from abomasal atony or chloride loss in the urine, are often found in ruminants with ARF.[170,174] Hyponatremia occurs after sodium loss in the urine. Because the kidney is the primary organ controlling magnesium excretion in ruminants, hypermagnesemia may occur in TN, particularly under conditions of high

magnesium intake.[170,175] Hyperphosphatemia results from reduced phosphorus excretion in saliva during anorexia, reduced urinary phosphorus excretion, and tissue hypoxia.[176,177] Hypocalcemia is also common in TN in ruminants because of reduced calcium intake, GI stasis, urinary losses, and the competitive effect of hyperphosphatemia.[170] Metabolic acidosis may develop in juvenile ruminants with TN and concurrent diarrhea.[177,178]

Fractional clearance (fractional excretion [FE]) of sodium has been used to help document renal failure in cattle.[178] Values of 0% to 4% have been described in normal cattle; age, ration, and metabolic status may affect FE values.[178] When applying this test, it is prudent to compare the patient's FE value for sodium to that of an age-matched herdmate in a similar physiologic state and on a similar ration. The normal values for several urinary diagnostic indices in healthy calves have been reported.[179]

34.41.4.2.9.4 Pathophysiology

34.41.4.2.9.4.1 ISCHEMIC AND HYPOXIC INJURY

Reduced blood flow to the kidneys most often occurs during generalized loss of vascular volume, as seen with marked blood loss, septicemia, endotoxemia, or severe dehydration. Oliguria or anuria is seen initially, and urine output varies after IV fluid therapy. These conditions may also cause infarction of the renal cortex and renal vein thrombosis.[170] Severe ruminal gas distention may impair renal perfusion.[170] Prolonged, severe ischemia may destroy the tubular basement membrane, thereby preventing tubular epithelial cell regeneration.[180]

34.41.4.2.9.4.2 TOXIC INJURY

The high metabolic demands of renal tubular epithelial cells render them susceptible to toxins that disrupt cellular enzymes. The injury caused by most nephrotoxins is compounded by dehydration, which concentrates the toxin in the tubular filtrate, slows toxin clearance, and if severe, reduces renal perfusion. Because some nephrotoxins are therapeutic agents, it is vital that the veterinarian monitors appetite, body weight, water intake, urine output, routine urine chemistry, serum drug concentration, and serum creatinine concentration during administration of these agents. Young or elderly patients, patients with preexisting renal insufficiency or sepsis, those receiving other potentially nephrotoxic drugs, and patients on prolonged or high-dose therapy with these agents warrant the closest attention.[181]

Table 34-2 Clinical Characteristics of Acute Toxic Nephrosis Caused by Common Nephrotoxins

Nephrotoxin	Clinical Findings*
Aminoglycosides	Usually nonoliguric, ototoxicosis possible; hematuria, glucosuria, proteinuria, increased serum trough concentration of drug
Tetracycline	Hematuria, glucosuria, proteinuria; possible hepatocellular enzyme elevation
Ionophores	Diarrhea, dark urine, dyspnea, cardiac dysrhythmias; elevated CK, AST, and indirect bilirubin
Ethylene glycol	Anuria or oliguria, tachypnea, ataxia, weakness; hemolysis, increased anion gap, increased serum osmolality, increased osmolar gap, acidosis, calcium oxalate crystalluria
Oxalate-containing plants, vitamin C	Hindlimb ataxia or paresis, apprehension, salivation; hypocalcemia, calcium oxalate crystalluria, aciduria, increased renal cortical echogenicity on ultrasonogram
Oak, acorns	Hemorrhagic diarrhea, ascites, hydrothorax, subcutaneous and perirenal edema; hyperfibrinogenemia, increased hepatic enzymes
Myoglobin	Muscle stiffness and weakness, dark urine; elevated serum CK and AST, positive reactions for blood and protein on urine chemistry strip, hemolyzed serum not present
Hemoglobin/methemoglobin	Icteric to pale mucous membranes, tachycardia, tachypnea, red or brown urine; positive blood and protein reactions on urine chemistry strip, anemia, elevated serum total protein, hemolyzed serum (hemoglobin only)
Arsenic	Colic, hemorrhagic diarrhea, ataxia; elevated blood and liver arsenic levels

CK, Creatine kinase; *AST,* aspartate aminotransferase.

* Many general clinical characteristics of acute tubular necrosis are also present. See Clinical Signs and Clinical Pathology.

34.41.4.2.9.5

Treatment and Prognosis

In cases of toxic nephroses, the animal should first be removed from the toxin source, or treatment with a nephrotoxic drug should be discontinued. *Rumenotomy,* with removal of toxic material, is most beneficial if performed soon (within 24 hours) after the animal has ingested a nephrotoxin. Activated charcoal (2 to 4 g/kg PO) may bind the agent in the gut lumen. The use of magnesium sulfate or other magnesium-containing laxatives should be avoided in such cases because severe hypermagnesemia may result in animals with concurrent compromise of renal function. If an animal is exposed to a potentially harmful quantity of a nephrotoxin, prophylactic diuresis through fluid therapy is warranted. In such cases, if the veterinarian were to wait for azotemia to appear before initiating fluid therapy, significant (>75%) loss of nephron function would occur before medical intervention.

The cornerstone of treatment of TN is restoration of adequate renal perfusion and urine production. This is most effectively achieved through IV administration of isotonic, sodium-containing fluids, with calcium and potassium supplementation as indicated. If cost or facilities make IV fluid therapy impractical, repeated administration of water and electrolytes by stomach tube is an option. A small-bore stomach tube can be passed through the nasal cavity into the rumen and secured to the animal's halter to allow one person to administer fluids repeatedly without the need for repeated tube passage. Placement of a small rumenostomy or securing in place a nasogastric tube allows one person to administer fluids repeatedly with relative ease. Administration of IV or oral fluids at 1.5 to 2 times the adult maintenance level of 60 mL/kg/day may be adequate to induce diuresis. The patient should be monitored for chemosis or labored or rapid respiration, which may be indicative of overhydration. Fluid therapy should be continued until azotemia resolves, at which time the patient's voluntary fluid intake can be assessed. Oral supplementation of potassium and calcium salts may be necessary in some cases, because it is often not possible to add adequate yet safe levels of these salts to IV fluids in cases of refractory hypokalemia and hypocalcemia, respectively.

Restoration of urine production is necessary in anuric or oliguric animals. If fluid therapy does not promote diuresis, furosemide (1 mg/kg IV or IM) may be administered. Repeated administration (every 1 to 2 hours) may be necessary to induce urine production in oliguric or anuric patients. With repeated use of furosemide, the patient's serum sodium and potassium concentrations must be monitored. Mannitol (0.25 g/kg IV) or dopamine (2 to 5 µg/kg/min IV) may be required to initiate urine flow if the previous measures are unsuccessful.

Lesions that occlude tubular blood flow (renal vein thrombosis, DIC) warrant a poor prognosis, whereas renal failure resulting from toxic causes carries a more favorable prognosis with early diagnosis and aggressive therapy. Return of appetite and progressive reduction in BUN and serum creatinine levels are positive prognostic indicators.[182] Prolonged supportive treatment (2 to 3 weeks) may be necessary to allow for regeneration of tubular epithelium in cases of acute TN.

34.41.4.3

LEPTOSPIROSIS

ROBERT J. CALLAN

Leptospirosis is a complex disease of both animals and humans caused by pathogenic species of *Leptospira*.[183–189] Pathogenic *Leptospira* species persist as chronic infections of the renal tubules of the maintenance host species, often causing little or no disease. Transmission to incidental hosts results from direct contact with urine from an infected maintenance host or through environmental and feed contamination with infected urine. Infection in the incidental host can cause acute disease in multiple organ systems, including the kidney, liver, and CNS, as well as result in abortion or reproductive failure. This discussion focuses on *Leptospira* infection and disease of the renal system of ruminants.

967

968

Leptospira is a diverse genus of motile, gram-negative, obligate aerobic, tightly coiled spirochetes approximately 0.1 to 0.3 µm in diameter and 6 to 20 µm in length.[183–185] The bacteria can survive in the environment for up to 6 months.[183,184,190] *Leptospira* species prefer a warm, moist environment with a pH of 7.2 to 8.0. Survival is short under dry conditions or at temperatures below 10°C.[183] *Leptospira* does not survive freezing in the envrironment.[191]

Before 1989, *Leptospira* was divided into the pathogenic species, *L. interrogans,* and the nonpathogenic saprophytic species, *L. biflexa*. The current taxonomy and classification of *Leptospira* use a complex system of both serologic and genetic characteristics.[184,185] Serologic classification is based on antigenic grouping of the lipopolysaccharide (LPS) and other outer surface antigens using the cross-agglutinin adsorption test (CAAT). More than 240 serovars are characterized. Antigenically related serovars are combined into larger serogroups, and serovars may also be further characterized into serotypes. Seventeen genomospecies have been identified based on DNA sequence heterogeneity.[184,185]

34.41.4.3.1

Epidemiology

Leptospirosis is predominantly observed under conditions where livestock come in direct or indirect contact with urine from an infected maintenance host (Table 34-3).[183–185,190] The prevalence of infection within a maintenance host population tends to be high (30% to 50%); in such populations, infection is often spread between animals by direct contact.[183] Transmission to incidental hosts is generally by contact with the environment, feed, or water that is contaminated with urine from an infected maintenance host. Transmission can also occur from contact with an infected fetus or uterine discharge. Survival of the bacteria in the environment and the incidence of infection in animals are increased in regions with warm, humid climatic conditions. The seasonal incidence is higher during the summer or fall in temperate regions and during the rainy season in warm-climate regions.[184] Environmental conditions that contribute to moist surroundings and foot abrasions may contribute to *Leptospira* transmission, particularly in housed dairy cattle.

Cattle are the primary maintenance host reservoir of *L. interrogans* serovar *hardjo* (type hardjopragitno) and *L. borgpetersenii* serovar *hardjo* (type hardjo-bovis). *L. interrogans* serovar *hardjo* (type hardjopragitno) is isolated primarily from cattle in the United Kingdom, and *L. borgpetersenii* serovar *hardjo* (type hardjo-bovis) is observed worldwide. Cattle can also serve as maintenance or incidental hosts for *L. interrogans* serovar *pomona* and *L. interrogans* serovar *grippotyphosa*.

Serovars *hardjo, pomona,* and *grippotyphosa* are most often implicated in renal infection of cattle.[192] Although data are scarce, renal disease caused by leptospirosis in small ruminants appears to be uncommon.[191,193] Sheep may serve as subclinical carriers of serovar *hardjo*.[187,194] Some serovars of *Leptospira* have zoonotic potential, and humans are always considered an incidental host.[183–185,188]

Table 34-3 Current Nomenclature, Maintenance Host, and Incidental Hosts for Common *Leptospira* Isolates in Ruminants

Genomospecies	Serovar	Maintenance Host	Incidental Hosts
L. interrogans	*Canicola*	Dogs	Cattle
L. interrogans	*Pomona*	Swine, opossums, skunks, racoons	Horses, cattle, sheep, goats, dogs
L. interrogans	*Icterohaemorrhagiae*	Rats	Dogs, cattle, swine
L. interrogans	*Bratislava*	Pigs, mice, horses	Dogs, cattle, horses
L. interrogans	*Hardjo* (type hardjoprajitno)	Cattle	Sheep, goats
L. borgpetersenii	*Hardjo* (type hardjo-bovis)	Cattle	Sheep, goats
L. borgpetersenii	*Ballum*	Mice	—
L. kirschneri	*Grippotyphosa*	Raccoons, muskrats, squirrels	Cattle, sheep, horses, dogs

An abattoir study of more than 5000 cattle in the United States identified approximately 2% renal carriers of *L. interrogans*.[192] Serovar *hardjo* was the most common renal isolate, followed by serovar *pomona* and serovar *grippotyphosa*. A study of Texas slaughterhouse cattle detected *Leptospira* species in 36% of urine samples by PCR. The seroprevalence for serovars *pomona* and *hardjo* was 22% and 15%, respectively.[195] A national survey showed 49% seroprevalence for *L. interrogans* serovars in cattle, with the highest seroprevalence found in cattle from southeastern, south-central, and Pacific Coast states.[196] Because contact with urine from infected animals is a means of transmission within cattle populations, high stocking density or confinement may increase the rate of infection in a herd.

In general, infection of cattle with the host-adapted serovar *hardjo* rarely results in acute, severe disease. If present, signs of disease are usually mild in acutely infected cattle and may simply present as cases of undifferentiated fever. Persistent, latent urogenital infection usually follows acute infection, with most overt losses attributable to adverse effects on reproduction.[188,197–199]

Acute, severe renal disease is more characteristic of incidental (also termed “accidental”) infection of cattle, particularly calves, with a non—host-adapted serovar of *Leptospira*. However, exceptions to this generalization do occur because host immunity and virulence of the organism are variable.[187,188]

34.41.4.3.2

Clinical Findings

Serovar *hardjo* is host-adapted to cattle, and many infections are asymptomatic or result in nonspecific reproductive failure or abortion. *Leptospira* serovar *hardjo* infection of cattle may produce chronic interstitial nephritis of variable severity, but overt renal dysfunction is rarely observed.[200] Chronic infection of the genital tract of cows and bulls is common.[189,201] Protracted shedding of the organism in the urine

often results, possibly lasting for the life of the animal.[200,201] Infertility, stillbirth, abortion, and birth of weak calves are typical clinical manifestations of infection with serovar *hardjo* in cows.[189,198,202,203] The fetus can be infected in utero, and if it survives the acute infection, it may be born persistently infected.[183] Fever, agalactia, and mastitis may occasionally occur, and the resulting syndrome has been termed the "milk-drop syndrome"[187] or "flabby udder."[188] The udder is uniformly soft, and the milk may be yellow- or red-tinged and thick.

In contrast, infection with the non—host-adapted serovars can result in severe systemic disease, hemolytic anemia, hepatitis, interstitial nephritis, and tubular nephrosis in calves and less often in adult cattle.[189,200] Meningitis is a rare manifestation.[193] Agalactia and mastitis often occur in lactating cows, and pregnant cows may abort. Urine shedding of non—host-adapted serovars by infected cattle can persist for weeks to months.[188,189,203] Renal lesions result from direct damage to the vascular endothelium during leptospiremia, hypoxia from endothelial damage and hemolysis, tubular epithelial damage from hemoglobin, and interstitial nephritis.[183,184,200] Some *Leptospira* serovars, particularly *pomona,* produce hemolysins that can cause acute intravascular hemolysis and anemia in cattle.

968

969

Clinical signs associated with acute infection may include fever, anorexia, lethargy, decreased milk production, petechiation, hemolytic anemia, and hemoglobinuria. Oliguria may be seen with interstitial nephritis or hemoglobinuric nephrosis. Elevated creatinine caused by pre-renal or renal causes may be observed on serum chemistry analysis. Examination of the urine may show proteinuria, pyuria, and cellular or granular casts in cases of nephritis. Hemoglobinemia and hemoglobinuria may be observed in patients with leptospire-induced hemolysis and can occasionally result in hemoglobinuric nephrosis.

34.41.4.3.3

Pathophysiology

Contaminated feed and surface water, wildlife, rodents, and domestic animals are potential sources of pathogenic serovars for cattle.[183,184,187,188] Leptospires penetrate external mucosal surfaces and scarified or macerated skin. The bacteria multiply locally during an incubation period that can last 2 to 20 days.[183,184] After the incubation phase, the organism enters the bloodstream through the lymphatics or by direct penetration into the blood vessel. Leptospiremia results in dissemination throughout the body and infection of multiple organs. This bacteremic phase lasts 4 to 7 days. Fever and other systemic signs are often present in clinically affected animals. Humoral antibodies can be detected at the end of the bacteremic phase. Opsonizing antibodies are generated and aid in clearing infection from most tissues in the host.

During the convalescent phase, leptospires may become localized in the mammary gland, kidney, or genital tract, where they appear to be protected from the immune response.[183,204] Depending on the virulence of the serovar involved, chronic renal infection may create few histologic changes, mild interstitial nephritis, or diffuse, severe, lymphocytic interstitial nephritis with fibrosis.[193] Nephritis may persist long after the host immune response has cleared the organism. Chronic infection of the kidney or reproductive tract allows for transmission of the organism in urine, uterine and vaginal secretions, placenta, fetal tissues, and semen.[187,189,201,205] Shedding in the urine may last for weeks to months with non—host-adapted infections. Renal shedding of host-adapted serovars can persist for months to years. The bacteria reside in the lumen of the renal proximal tubules, where they are protected from phagocytes and humoral antibodies. The bacteria do not stimulate a systemic immune response while localized in the proximal tubule lumen, and thus serum antibody titers can decline and become negative even though the kidney is infected and shedding bacteria.

Multiple potential virulence factors may contribute to leptospirosis.[184,185] Leptospiral LPS and outer membrane proteins are believed to contribute to the development of interstitial nephritis. However, leptospiral LPS has different biochemical properties that make it less toxic than other gram-negative lipopolysaccharides. Motility is an important pathogenic mechanism and contributes to invasion and dissemination of the bacteria. As many as 50 genes are related to leptospiral motility.[185] Pathogenic *Leptospira* strains produce chemotaxis proteins, and some strains exhibit chemotaxis toward hemoglobin. Adherence to cells is in part conferred by fibronectin-binding protein present on the surface of pathogenic strains but not on nonpathogenic strains. Leptospiral immunoglobulin-like protein A (LigA) may also be involved in attachment and invasion. Additional proteins that may contribute to virulence include hemolysins, sphingomyelinase C, sphingomyelinase H, and hemolysis-associated protein 1 (HAP-1).[184,185]

34.41.4.3.4

Diagnosis

The microscopic agglutination test (MAT) is the most widely used serologic test for the diagnosis of leptospirosis in cattle. The MAT detects antibodies to specific serovars, but cross-reactivity occurs between related serovars, particularly within the same serogroup. Thus, an infection with one strain may result in increased MAT titer to multiple serovars. Serum antibody enzyme-linked immunosorbent assay (ELISA) tests have been developed for research but have not yet been adopted in the routine clinical diagnostic setting for animals.[206–209]

An elevated serum antibody titer is observed after the bacteremic phase and is suggestive of *Leptospira* infection when associated with concurrent clinical signs. However, interpretation of a single titer is problematic in vaccinated animals or when endemic exposure is suspected.[189,204] A fourfold increase in MAT titer between acute and convalescent serum samples, or conversion from a negative titer to a titer of 1/100 or greater, supports a diagnosis for both host-adapted and non—host-adapted serovars. However, vaccinated animals may have a diminished serologic response after challenge and renal colonization with *L. borgpetersenii* serovar *hardjo*.[210] Serologic detection of persistent infection with serovar *hardjo* can be difficult because paired serum titers may be increasing, static, decreasing, or undetectable at examination (e.g., at abortion).[189,204] It is generally recommended to consider the serovar with the highest titer as being the infecting strain. However, recent studies demonstrate that serologic antibody titers may not accurately predict the infecting strain in humans because of cross-reaction between different serovars within the same serogroup.[211] Consultation with a clinical immunologist affiliated with the laboratory performing the MAT is recommended for accurate interpretation of results.

Leptospira shedding in urine and semen can be detected by multiple tests, including urine culture, phase-contrast microscopy, darkfield microscopy, fluorescent antibody (FA), polymerase chain reaction (PCR), nucleic acid hybridization, and immunoblot.[192,204,205,212–214] Urine cultures are often unrewarding because of the fastidious nature of the organism, and conclusive results may not be obtained for up to 6 months.[205] Both FA and PCR assays are typically used by veterinary diagnostic laboratories to identify *Leptospira* species from urine samples. Neither of these tests will determine the infecting serovar. The sensitivity of detecting *Leptospira* shedding can be improved by performing two tests on a single sample.[205,214] Evaluation of serovar-specific antibody titers from positive animals may aid in identification of the infecting serovar.

Second-voiding urine samples collected after the administration of IV furosemide are recommended for urine testing.[191,215] Furosemide is administered at 0.5 to 1.0 mg/kg IV or IM, and the first-voided urine is discarded. A second urine sample is then collected after cleaning the vulva of gross debris. Approximately 10 mL of urine should be collected and stored on ice (not frozen) for transport to the diagnostic laboratory. Urine from 10 to 15 adult animals should be tested when evaluating a herd for endemic *Leptospira* serovar *hardjo* infection.

Biopsy or necropsy samples of renal tissue may be treated with Warthin-Starry or Levaditi silver stains for microscopic examination.[193] Immunoperoxidase staining was shown to be more sensitive for identifying *Leptospira* species in kidney and liver of naturally infected cattle than Levaditi silver stain.[216]

969

970

34.41.4.3.5

Treatment and Prognosis

Treatment of acute leptospirosis caused by non—host-adapted serovars should focus on the elimination of the bacteria, systemic support, and diuresis if renal involvement is observed. In vitro susceptibility has been demonstrated for several antibiotics that could be used in food-producing ruminants, including ampicillin, amoxicillin, penicillin G, erythromycin, tetracycline, tylosin, and tilmicosin.[203,217–219] Oxytetracycline (10 to 15 mg/kg IM twice daily) and dihydrostreptomycin (12.5 mg/kg IM twice daily) have been recommended for treatment of acutely infected cattle.[191] Nephrotoxicosis is a potential concern with this dosage of oxytetracycline in cattle with preexisting renal disease, and dihydrostreptomycin is not currently available for use in cattle in the United States. Penicillin (25,000 IU/kg IM twice daily) and sodium ampicillin (20 mg/kg IM twice daily) have been suggested for treatment, but the efficacy of these regimens in cattle remains unproved.[191] In humans, doxycycline (100 mg every 12 hours for 7 days) has been shown to reduce the duration and severity of illness.[184]

Intravenous or oral fluids and nonsteroidal antiinflammatory drugs (NSAIDs) may be indicated for systemic support. In animals with severe hemolysis, blood transfusion may be considered. Renal diuresis should be established in animals with hemoglobinuria or evidence of ARF from pigment nephrosis or interstitial nephritis. The prognosis for renal disease caused by leptospirosis is influenced by the virulence of the serovar involved, host immunity, and the extent of renal lesions. Cases with renal azotemia warrant a guarded prognosis because more than 75% of nephrons are affected in such cases, and chronic interstitial nephritis and fibrosis may occur after treatment of the acute disease.

Chronic renal infection with *Leptospira* serovar *pomona* in cattle can be eliminated with a single injection of dihydrostreptomycin (25 mg/kg IM), although spontaneous clearance of this serovar often occurs in cattle.[191,203] Conflicting data exist on the efficacy of this treatment in clearing renal infection with serovar *hardjo*.[220,221] Long-acting oxytetracycline (20 mg/kg IM or SC, two doses 10 days apart) has been recommended to treat chronic leptospiral infections or reduce the risk of introduction of infected animals into a herd.[187] Oxytetracycline (20 mg/kg IM once), ceftiofur (2.2 mg/kg IM every 24 hours for five treatments), and tilmicosin (10 mg/kg SC once) have been shown effective in clearing renal shedding of *L. borgpetersenii* serovar *hardjo* from experimentally infected cattle.[222]

34.41.4.3.6

Prevention

Draining or fencing off standing water may reduce transmission. Maintaining a dry, clean environment may also help reduce exposure and infection. Limiting rodent and wildlife contact with cattle and their feed and water is often difficult to accomplish, but it reduces the potential for transmission of non—host-adapted leptospires.[189] For host-adapted *Leptospira* serovar *hardjo,* it is necessary to prevent or eliminate the renal carrier state in infected cattle in order to reduce transmission.

Vaccination is regarded as an effective means of preventing losses from leptospirosis. Conventional pentavalent (*L. canicola, grippotyphosa, hardjo, icterohaemorrhagiae,* and *pomona*), whole-cell, inactivated leptospiral vaccines are recommended in calves and adult cattle as an aid to prevent clinical disease caused by *Leptospira* species. However, these conventional pentavalent vaccines may not consistently prevent renal colonization and shedding after challenge with host-adapted *L. borgpetersenii* serovar *hardjo* (type hardjo-bovis).[223,224]

A monovalent *L. borgpetersenii* serovar *hardjo* (type hardjo-bovis) vaccine (Spirovac, Pfizer Animal Health, New York) is licensed for the prevention of *Leptospira* serovar *hardjo* infection, including reproductive and renal tract colonization, and urinary shedding for up to 12 months. This vaccine stimulates an immune response characterized by IgG_1 and IgG_2 agglutinating antibodies, as well as antigen-specific T-cell production of interferon gamma (IFN-γ).[210,225–227] The strong IFN-γ response is consistent with induction of a type 1 immune response and may be responsible for antibody class switching to IgG_2, which is a more potent opsonin than IgG_1.[225] Combination pentavalent *Leptospira* vaccines have been developed that also promote high *L. hardjo* antibody titers, in addition to the other serovars contained in the vaccine (Vira Shield 6+$L5^{HB}$, Novartis Animal Health US, Greensboro, NC; Vista 5 L5 SQ, Intervet, Millsboro, Del). Because *Leptospira* species are largely extracellular pathogens, the relevant protective immune response appears to be antibody-mediated neutralization and opsonization during leptospiremia.[184,185] There is no indication that cytotoxic immunity is a relevant immune response for protection or resolution of leptospirosis.

Although these vaccines help prevent colonization and shedding of *leptospira* serovar *hardjo* from the kidney, they are not effective in resolving current renal infection and elimination of the carrier state. Thus, vaccination at an early age followed by annual boosters is recommended to prevent initial renal colonization. Renal shedding in previously infected animals can be resolved by antibiotic treatment, and vaccination can be used to prevent future colonization.

34.41.4.4

CONGENITAL DEFECTS

DAVID C. Van METRE

Most severe congenital defects of the urinary tract of ruminants manifest at an early age, although occasionally defects remain clinically occult until adulthood.[228] Congenital defects of the urinary system should be considered in the differential diagnosis for a young animal with renal disease or abnormal urination. However, tubular necrosis caused by severe volume depletion, nephrotoxins, and infectious diseases are much more common. If a congenital defect of the urinary tract is identified, a careful examination of other body

systems should be performed; 73% of lambs with urogenital defects were found to have one or more defects in other organ systems.[229] Urogenital defects in ruminants are described in Chapter 51.

34.41.4.4.1 Renal Defects

Renal cysts are considered to be a common bovine renal defect[230] and have been described in sheep[229] and a goat.[231] These fluid-filled cavities in the renal parenchyma are usually of no clinical significance unless they are large or numerous (polycystic kidneys).[228,230] *Renal agenesis* was found to be the most common renal defect in lambs, with hydronephrosis and renal dysgenesis occurring less frequently.[229] A retroperitoneal, perirenal *pseudocyst* (a fluid sac lacking an epithelial layer) has been reported in a ram with acute abdominal pain.[232] Pseudocysts typically develop as outpocketings of the renal capsule and can develop as a result of renal trauma, urinary tract obstruction, or vascular or lymphatic anomalies.

Renal oxalosis is a metabolic disease of beefmaster calves that is suspected to have an inherited basis. The calves show weakness, lethargy, and anorexia within days to several weeks of age. Alopecia over the head, neck, and extremities; dehydration; and diarrhea may also be seen. Evidence of renal failure is found on serum chemistry analysis. An inherited abnormality of glycine or glyoxalate metabolism may generate high levels of endogenous oxalate, which readily complexes with calcium. As a result, calcium oxalate crystals accumulate in the renal tubules, obstructing outflow of the tubular filtrate. Exposure to oxalate-containing plants and ethylene glycol must be ruled out in all cases of renal oxalosis.[233]

970

971

34.41.4.4.2 Ectopic Ureter

Ectopic ureter is a rare congenital defect in which one or both ureters terminate in an abnormal location. An ectopic ureter may terminate in the urethra, vagina, or cervix or caudal to the bladder trigone in females. In males the ectopic ureter usually terminates in the urethra, vas deferens, or seminal vesicles. Urinary incontinence is the most common presenting complaint for affected animals.[234] Urine dribbling results in scalding of the perineum and medial surfaces of the hindlimb in heifers, and scalding in males is usually located on the prepuce and ventral abdomen. Occasional episodes of normal micturition may be seen. UTI, polycystic kidney(s), and hydronephrosis may exist concurrent to ectopic ureter(s).

Definitive diagnosis requires IV contrast urography or endoscopic examination of the urinary tract. Options for surgical correction include transposition of the ectopic ureter(s) or, in the case of unilateral involvement, ipsilateral nephrectomy. The latter option is valid only if the contralateral kidney is functional, as determined by blood chemistry, and structurally normal or near normal, as determined by ultrasonography or IV pyelography. The use of affected animals for breeding should be discouraged.

34.41.5 NEOPLASIA

DAVID C. Van METRE

Other than those associated with ingestion of bracken fern, primary neoplasms of the urinary tract of ruminants are rare. In a North American abbatoir survey, primary tumors of the bladder were detected in 0.05% of more than 21,000 cattle examined, with cases of papillomas, adenomas, and transitional cell carcinomas identified in the sample population.[235]

Renal carcinoma has been described in cattle,[236,237] and nephroblastoma has been documented in a ewe and an aborted lamb.[238] Renal involvement may be seen in occasional cases of lymphosarcoma in ruminants. Single cases of lymphoma involving the urinary bladder of a cow[239] and a goat[240] have been reported.

35 Chapter 35 Diseases of the Nervous System

Mary O. Smith

Consulting Editors

Lisle W. George

35.1 CEREBROSPINAL FLUID

Cerebrospinal fluid (CSF) is partly derived from and in equilibrium with the extracellular fluid that bathes the brain and spinal cord parenchyma.[1–3] CSF has been shown to act as a "sink" for brain extracellular fluid,[4] and its composition is an indicator of the state of the intrathecal milieu. CSF is produced by a combination of ultrafiltration of plasma and active secretion.[5] The sites of CSF production are the choroid plexuses of the lateral, third, and fourth ventricles; the ependymal lining of the ventricular system; the pia arachnoid; and the meningeal blood vessels. The CSF in the ventricular system flows caudally and diffuses out of the lateral apertures in the fourth ventricle. It then circulates around the brain and the spinal cord. Circulation of CSF is achieved through regional pressure changes caused by spinal motion and pulsations of blood vessels. Resorption of CSF occurs from both the cranial cavity (75%) and the spinal canal (25%).[6] Some resorption of brain CSF occurs at the arachnoid villi associated with large veins and sinuses, but recent studies have shown that most resorption occurs at the cribriform plate, into nasal lymphatics.[7,8] Resorption of spinal CSF occurs into the lymphatics associated with spinal nerves.

The predominant direction of CSF flow in the spinal canal is caudal; thus, changes in CSF caused by lesions within the nervous system occur predominantly caudal to lesions. CSF can be collected from the cisterna magna when the site of interest is the brain, whereas it should be collected from the lumbar subarachnoid space when the lesion is in the spinal cord. In large animals, however, the risks associated with the general anesthesia required for cisterna magna tap are considerable, so lumbar puncture is usually the most suitable technique for CSF collection in these species, regardless of the site of the lesion.[9,10]

35.1.1 COLLECTION OF CEREBROSPINAL FLUID

35.1.1.1 Lumbosacral Spinal Tap

Collection of CSF from the lumbosacral cistern is preferred for most large animal patients and is always done when the lesion is located in the spinal cord. Because the predominant flow of CSF is caudal, fluid collected from the cisterna magna reflects only changes within the brain and the most cranial parts of the spinal cord. However, fluid collected from the lumbosacral site is altered by either brain or spinal cord disease. Once a neuroanatomic diagnosis has been made, therefore, the site most suitable for collection can be chosen.

For collection of CSF by lumbosacral puncture, the animal is lightly sedated, and the skin of the dorsal midline over the junction of the sixth lumbar (L6) and first sacral (S1) vertebrae is surgically prepared (Fig. 35-1). A variety of standard sedative protocols are suitable, although xylazine has been shown to reduce CSF pressure.[11] Correct placement of the spinal needle is more easily achieved with the animal standing. The proper anatomic site for insertion of the spinal needle is between the dorsal spinous process of L6 cranially

and S1 caudally and the two tuber sacrales laterally. The overlying skin forms a depression that can be recognized by palpation, although this may be difficult in well-muscled horses. The correct site for needle placement can also be located by determining (1) the dorsal midline at the “highest point” of the quarters or (2) the point where a line drawn between the caudal aspects of the two tuber coxae intersects the midline.

The skin is anesthetized with 2% lidocaine, and a 1-cm incision is made with a No. 15 scalpel blade. A 6- to 9-inch, 18- to 20-gauge spinal needle is inserted perpendicularly through the incision and advanced until the tip punctures the lumbosacral cistern (a 3½-inch needle can be used in small ruminants, foals, and most cattle). A “snapping” sensation sometimes is felt as the needle passes through the interarcuate ligament. The patient may reflexly contract the tail, anus, and gluteal muscles. Some patients, particularly horses, may respond with violent motor activity. For this reason, a lumbosacral spinal tap performed on a conscious horse should be done only when the animal is restrained in stocks; people have been severely injured when this rule was not followed. The average depth of insertion is 17.64 cm (7 inches) in horses, 8.26 cm (3⅓ inches) in ponies,[10] and about 7.5 cm (3 inches) in adult cattle.

The spinal needle is advanced gently to the floor of the spinal canal. Passage of the needle through the terminal spinal cord or the cauda equina does not cause subsequent neurologic abnormalities. When the needle is seated in the spinal canal, very gentle negative pressure can be applied by withdrawing spinal fluid into a series of 3-mL syringes. If frank blood is obtained, the tip of the needle probably is in one of the ventral vertebral sinuses. The needle should be withdrawn a few millimeters and a clean syringe attached to the hub. Compression of the jugular vein causes engorgement of the ventral vertebral plexus, which increases CSF pressure in the lumbosacral cistern. Failure of the CSF to flow from the needle after compression of the jugular vein could indicate incorrect needle placement or an obliterative lesion of the thoracolumbar spinal cord.

35.1.1.2

Cisterna Magna Tap

General anesthesia is required for a cisterna magna tap. After the patient has been anesthetized, the dorsal area of the neck overlying the atlantooccipital joint is surgically prepared. The patient's head is held flexed at a right angle to the neck, with the sagittal plane of the head parallel to the floor or table on which the patient is lying. The head must not be allowed to move while the needle is inserted. The needle is inserted at 1 to 2 cm caudal to a point corresponding to the intersection of the dorsal midline and a line drawn between the cranial aspects of the wings of the atlas. This point usually is 6 to 9 cm (2½ to 3½ inches) from the poll (Fig. 35-2). A 3½-inch, 18-gauge spinal needle is inserted perpendicular to the skin and aimed toward the nose. The needle is advanced slowly with the stylet seated. After the needle has been advanced a few millimeters, the stylet is removed and the hub of the needle examined for CSF flow. The stylet is replaced if it is dry and CSF is not spontaneously dripping from the hub, and the needle is advanced another few millimeters and checked again for CSF flow. Entry of the tip of the needle into the cisterna magna may be accompanied by the sensation of “popping” through a tissue plane or by a sudden decrease in resistance to the advancement of the needle. In other cases, however, no such sensation is perceived, thus the precaution of checking for CSF flow every time the needle is advanced a few millimeters.

Fig. 35-1 Close-up view of landmarks for a lumbar cistern puncture in a horse. The large dark ovals *(A)* represent the position of the two tubers sacrale. The smaller curved lines *(B)* represent the respective caudal and cranial aspects of the L6 and S1 dorsal spinal processes. The dotted line represents the optimum area for placement of a skin stab.

Fig. 35-2 View of the ideal area for a cisterna magna cerebrospinal fluid tap in a cow. The two lines *(a)* represent the wings of the atlas. The large spot in the center *(b)* is the optimum area for needle insertion. It is essential to prevent head movement by use of anesthesia and restraint.

In most large animals the needle is seated at approximately 5 to 8.75 cm (2 to3½ inches). While advancing the needle, the heel of the hand should be held firmly against the animal's neck to minimize the possibility of spinal cord injury. The mean depth of insertion is 6.16 cm (2½ inches) in horses[10] and 5.08 cm (2 3½ inches) in cattle. In a cisterna magna tap, the needle entry site is close to the cervical spinal cord and the brainstem. To minimize the danger of central nervous system (CNS) damage during a cisterna magna tap, the animal should be adequately anesthetized and ventilated, because an increased partial pressure of carbon dioxide (P_{CO_2}) results in elevated intracranial pressure.[12] Removal of fluid from the cisterna magna is contraindicated in a patient with increased intracranial pressure because a possibly fatal herniation of the brain through the foramen magnum and under the tentorium cerebelli may occur. Signs of increased CNS pressure include a moderate to marked decrease in mentation, mydriatic pupils, opisthotonos, extensor rigidity, ventrolateral strabismus, and papilledema.

Ultrasonography can be used as an aid to needle placement for collection of CSF from both the atlantooccipital cistern and the lumbosacral subarachnoid space.[13,14] In the authors' experience, however, CSF collection can usually be effected without such assistance.

35.1.1.3

Myelography

Contrast material for myelography is injected into the cisterna magna in large animal patients. Withdrawal of CSF before injecting the contrast medium is unnecessary, and reinjection of CSF after it has been withdrawn is inadvisable. The turnover of CSF is rapid and under strict homeostatic control; therefore, withdrawal of CSF through a spinal tap does not have deleterious effects that require its replacement.[15–17] In horses undergoing myelography, two spinal needles can be placed, one at the lumbosacral space and one into the cisterna magna. As the contrast medium is injected through the needle in the cisterna magna, CSF is allowed to drain freely from the lumbar needle. This technique facilitates injection of large volumes of contrast material but is not absolutely necessary to obtain a good-quality myelogram.

35.1.2

ANALYSIS OF CEREBROSPINAL FLUID

The color of the CSF should be noted as it flows from the hub of the spinal needle. Blood can originate from the tapping procedure (iatrogenic hemorrhage) or from a traumatic CNS lesion. Iatrogenic hemorrhage is unevenly mixed in the CSF and disappears as the fluid drips from the needle. Fluid collected immediately after placement of the spinal needle tends to be mildly contaminated with blood even when this is not apparent grossly. Successive aliquots usually are less contaminated, so the later aliquots are most suitable for cellular and protein analysis.???[18] Blood resulting from CNS hemorrhage is evenly mixed with CSF even after a large amount has been removed. Hemorrhage that has occurred days earlier may have a brownish rather than red discoloration. Prior hemorrhage also results in *xanthochromia,* a yellow discoloration of the CSF. Xanthochromia can be observed in the CSF for at least 10 days after the introduction of blood. Xanthochromic samples do not contain bilirubin.

973

974

Fig. 35-3 Black cerebrospinal fluid from a lumbosacral tap of a gray horse with paraparesis. The animal had a melanoma that infiltrated the caudal spinal rootlets.

Other abnormalities may be noted in CSF. For example, a black discoloration is diagnostic of a melanoma (Fig. 35-3). Foamy CSF denotes a protein concentration greater than 200 mg/dL, and turbid CSF usually denotes cell counts exceeding 400 mg/dL.

The normal values for CSF are presented in Table 35-1. Cell counts should be determined in a noncentrifuged specimen as soon as the sample is collected, using a hemacytometer. Automated methods for counting cells are

not suitable for CSF because the very low numbers of cells in CSF compared to blood result in erroneous counts. Morphologic examination of cells from CSF is most suitably done on cytospin preparations in an appropriately equipped laboratory, but sedimentation and membrane filtration techniques for CSF cell preparations have been described.[19,20] Normal CSF from large animals contains fewer than six white blood cells (WBCs) per deciliter. Some reports have documented occasional WBC counts greater than 40 cells/dL in the CSF of normal horses.[21] Although suggested to correct for the effects of iatrogenic blood contamination, various "correction factors" are inaccurate and should not be used.[18,22]

Table 35-1 Normal Range of Values in Cerebrospinal Fluid for Large Animals[1,4,5]

Component	Unit	Equine	Bovine	Ovine	Caprine
Specific gravity		1.004–1.008	1.004–1.008	NA	NA
Refractive index		1.3343–1.3349	1.3343–1.3349	NA	NA
Protein	mg/dL	5–100	20–40	8–70	24–40
White blood cells (WBCs)	WBCs/dL	0–6	0–3	0–5	0–7
Glucose	mg/dL	30–70	35–70	48–109	45–87
Sodium	mEq/L	140–150*	132–144*	145–157*	NA
Potassium	mEq/L	2.5–3.5	2.7–3.2	3–3.3	3
Creatine kinase	IU/L	0–8	2–48	NA	NA
Magnesium	mEq/L	NA	1.7–2.7	NA	NA

NA, Result not available.

* Cerebrospinal fluid (CSF) sodium is the same as serum or plasma sodium when measured with ion-specific electrodes. When other measurements are used, the CSF sodium is usually higher than plasma sodium.

The refractive index of normal CSF is less than 1.335. The protein concentration of CSF in normal adult ruminants is less than 50 mg/dL and in normal horses less than 100 mg/dL, although reference values vary with the techniques used for protein measurement; reference values should be established for each laboratory.[23] Nephelometry is usually used for measurement of CSF protein in commercial laboratories. Protein electrophoresis has been performed on CSF to identify particular patterns associated with specific diseases;[24] however, conflicting results limit the clinical application of this technique.[25]

Studies of the specific and relative quantities of albumin and immunoglobulins, particularly IgG and IgM, have been stimulated by the increasing importance of immunologic testing of CSF for diseases such as equine protozoal encephalomyelitis. Reference values for a number of parameters have been established.[26] The most important of these parameters are *albumin quotient,* a measure of blood-brain barrier (BBB) permeability, and *IgG index,* a measure of intrathecal production of IgG.[27] The formulae for these parameters are as follows:

$$\text{Albumin quotient} = (\text{CSF albumin} / \text{Serum albumin}) \times 100$$

$$\text{IgG index} = (\text{CSF IgG} / \text{Serum IgG}) \times (\text{Serum albumin} / \text{CSF albumin})$$

Reference values must be established for each species. An elevated albumin quotient indicates BBB leakage or contamination of CSF with blood, with possible introduction of immunoglobulins from serum. An elevated IgG index indicates intrathecal production of IgG and may support a diagnosis of infectious disease of the CNS. The usefulness of these parameters is influenced by a number of other variables, including the immunoreactivity of blood.[28] Therefore, clinical interpretations must be made with great caution.

The concentrations of glucose and protein in the CSF of newborn foals are almost twice those found in the CSF of adults, but they approximate adult normal values by 2 weeks of age.[29] In contrast, calves between 1 and 2 months have lower protein concentration and higher leukocyte numbers in CSF than adult cattle.[30] The reference values for CSF proteins of normal horses and cattle are presented in Table 35-2.

Neural tissue contains the BB isoenzyme of creatine kinase (CK), which increases after damage to the nerve cells.[31,32] The molecule does not cross the BBB, so CK in the CSF originates from neural tissue. Contamination of CSF with dura or fat, however, falsely elevates the CK concentration. Some have suggested that CK is an accurate marker and a prognostic indicator for CNS disease, but other studies have not supported this conclusion, and measurement of CK, although interesting, has limited clinical utility.[31,33,34]

974

975

Table 35-2 Protein Composition* of Cerebrospinal Fluid in Horses and Cattle[3–5,10]

Factor	Horses	Cattle
Albumin	22.6–67.9* (55.1)	8.2–28.7 (15.7)
Total globulin	3.8–20.1 (10.5)	NA
Total alpha	0.51–12.8 (0.46)	9.7–24.3 (14.7)
$Alpha_1$	0.18–10.6 (0.48)	NA
$Alpha_{2a}$	0.1–0.76 (0.31)	NA
$Alpha_{2bc}$	0.23–1.44 (0.59)	NA
$Beta_1$	0.38–3.36 (1.59)	1.875–8.85 (3.8)
$Beta_2$	0.27–1.31 (7)	NA
Gamma	0.27–3.03 (1.35)	2.45–8.85 (4.8)

NA, Result not available.

* Range of values for protein concentration is expressed in mg/dL; numbers in parentheses are mean values.

The normal CSF concentration of glucose is approximately 80% of that in blood. A decline in the ratio of CSF to serum glucose occurs in animals with bacterial meningitis because of increased use of glucose by inflammatory cells.

Measurement of the sodium concentration of the CSF may be helpful for diagnosing salt poisoning in cattle. In animals that do not have salt poisoning, this value is always less than 160 mmol/L; in animals with salt poisoning, the concentration usually is greater than 180 mmol/L.

35.1.3 TESTING CEREBROSPINAL FLUID FOR SPECIFIC DISEASES

Testing CSF for antibodies to a variety of infectious agents is now possible, as discussed later for specific diseases.

Measurement of neurotransmitters and several biomarkers for CNS injury is currently available in the experimental setting.[35] Studies of these substances aid our understanding of CNS physiology and pathology. Large animal species frequently are used as experimental models in such research, thereby enhancing our knowledge of CSF in health and disease in these species. Quantitation of neuropil-specific proteins (e.g., glial fibrillary acidic protein, neurofilament proteins), a variety of cytokines, nitric oxide metabolites, and neurotransmitters (e.g., nociceptin) is proving useful in elucidating the mechanisms of CNS injury and, in some cases, quantitating its severity.[36,37] Although these tests are not yet commercially available, this may change in the future, facilitating the clinician's ability to determine the prognosis for patients with CNS injury or disease.

35.2 DISEASES PRODUCING CORTICAL SIGNS

35.2.1 MAEDI-VISNA VIRUS INFECTION (OVINE PROGRESSIVE PNEUMONIA VIRUS INFECTION; ZWOEGERZIEKTIE)

35.2.1.1 Definition and Etiology

Maedi-visna virus, or ovine progressive pneumonia virus (OPPV), infection is a chronic disease of sheep caused by a retrovirus (subfamily Lentivirinae).[38–49] Visna virus is closely related to the many lentiviruses that cause immunodeficiency and neurologic disease in other species; these viruses include equine arteritis virus, caprine arthritis-encephalitis virus, and simian, feline, and human immunodeficiency viruses.[50,51] Caprine and ovine lentiviruses constitute a single virus group, termed the *small ruminant lentiviruses* (SRLVs), which can readily cross between species.[52–54] These agents are enveloped ribonucleic acid (RNA) viruses that contain reverse transcriptase.[55,56] The respiratory aspects of the viral infection are discussed in Chapter 31.

35.2.1.2 Clinical Signs

Neurologic disease caused by maedi-visna virus is relatively rare.[51] Nervous system signs may be characteristic of a diffuse encephalitis and include ataxia, twitching of the facial muscles, conscious proprioceptive deficits, normal gait along a straight path, staggering or stumbling when turned or forced to perform a complex maneuver, circling, and blindness. Coma, convulsions, and hyperexcitability may be seen in terminal stages. Other sheep have gradually progressive limb weakness and ataxia, often worse in the rear limbs; myelitis may be the sole clinical manifestation of maedi-visna.[56,57] Some sheep merely show emaciation without neurologic signs. The time between the onset of clinical signs and death may be as long

as 1 to 2 years. Because of the slowly progressive nature of OPPV infection and the high probability that affected sheep eventually will develop chronic disorders of the nervous, musculoskeletal, mammary gland, or respiratory system, the presence of antibody in the serum usually is considered evidence of active infection.[58,59]

35.2.1.3

Clinical Pathology

The CSF of affected animals is characterized by pleocytosis, with the cell counts per deciliter ranging from 1012 to 1478 for animals infected for 1 month and 4 years, respectively.[60] The protein concentrations of CSF range from 50 to 100 mg/dL for 30 days after infection. Antiviral antibody and virus can be detected in CSF specimens. The CSF/plasma ratio of immunoglobulin G (IgG) in the CNS is normal (<0.2) during the first month after infection but rises to over 0.4 after 1 month.[61]

35.2.1.4

Pathophysiology

The lesions of maedi-visna virus infection are partly induced by the host's inflammatory response. Experimental immunosuppression of infected sheep ameliorates the severity of the clinical signs and reduces the pathologic lesions of the cerebral cortex without altering the amount of viral shedding.[62,63] The virus is immunosuppressive. Viral infections usually lead to a variety of secondary bacterial infections.[64] Spread of OPPV within the tissues and secretion of the virus may be facilitated by concurrent diseases, such as *Brucella ovis*.[65] The chronic viremia may be caused by repeated antigenic changes of the virus; by intermittent expression of proteins by persistent proviral deoxyribonucleic acid (DNA) in cells; or by protection of the virus in circulating immune cells. Natural resistance to maedi-visna virus infection may be mediated partly by a nonimmunoglobulin inhibitory substance that is present in ovine plasma.[64]

35.2.1.5

Pathology

Gross lesions of visna infection are seen only rarely, when inflammation and malacia are extensive. In such cases, areas of yellowish tan discoloration are present in white matter.[66] The microscopic lesions of visna are predominantly those of a diffuse, nonsuppurative, perivascular inflammation throughout the neuraxis, affecting white matter in particular, although gray matter also is involved. The lesions include demyelination, gliosis, lymphocytic choriomeningitis, round cell infiltration of the choroid plexus, and focal necrotic areas that are infiltrated by macrophages.[67,68] Inflammatory lesions are predisposed to develop in a periventricular location, including around the central canal of the spinal cord.

975

976

After exposure to the virus, sheep develop an asymptomatic infection for as long as 6 weeks. During this time the virus can be isolated from the brain and other tissues; later the virus can be isolated from peripheral blood neutrophils but not from tissue homogenates, indicating that replication of the virus occurs in circulating cells during this stage of the infection.[69] Once the disease has been recognized, the affected sheep should be culled or slaughtered. Rigid control measures that may be partly successful[46] are discussed in Chapter 31.

35.2.1.6

Diagnosis and Epidemiology

Spread of maedi-visna virus occurs through ingestion of infected milk by neonates, through in utero transmission, and horizontally within a herd. Recent data suggest that the role of colostrums and milk in the spread of disease may be less important than previously thought, and that seropositivity in young lambs may be caused by colostral antibodies rather than true seroconversion by the lambs.[48,70] Low prevalence of the virus within herds managed extensively rather than intensively further supports the belief that horizontal transmission is the most important mode of infection.[71]

The diagnosis of visna infection is made initially by recognition of the clinical neurologic disease in groups of animals in which the pulmonary form of the disease also is present. Agar gel immunodiffusion (AGID) testing has been superceded by more accurate enzyme-linked immunosorbent assay (ELISA) and polymerase chain reaction (PCR) tests.[51,72–75] The diagnosis and epidemiology of maedi-visna virus infection are discussed in detail in Chapter 31.

35.2.1.7

Treatment and Prevention

No effective treatment for maedi-visna virus infection is available for field use, although the disease has been used as an animal model system for the study of drugs effective against lentiviruses.[76,77] Prevention is based on herd hygiene and culling of affected animals. Recently, a novel vaccine strategy using a plasmid encoding for viral envelope glycoproteins has shown some promise, although routine clinical use of such vaccines is probably many years away.[78]

35.2.2

CAPRINE ARTHRITIS-ENCEPHALITIS VIRUS INFECTION (INFECTIOUS LEUKOENCEPHALOMYELITIS)

35.2.2.1

Definition and Clinical Signs

The caprine arthritis-encephalitis (CAE) virus belongs to the retrovirus group and is closely related to the virus that causes maedi-visna and ovine progressive pneumonia in sheep ("small ruminant lentiviruses").[79] The systemic manifestations of the disease are thoroughly discussed in Chapter 38. The leukoencephalomyelitis form of CAE is predominantly seen in young goats but may occur in goats as old as 22 years.[80] The clinical signs of leukoencephalomyelitis include ataxia, paraparesis, paraplegia, tetraparesis, tetraplegia, hemiparesis, hemiplegia, head tilt, nystagmus, tremors, torticollis, trismus, salivation, depression, coma, and opisthotonos.[81–87] The neurologic deficits may be either symmetric or asymmetric. Goats with high cervical spinal cord lesions (L1 to L4) are recumbent and unable to raise their heads from the floor. They may show resistance to passive neck flexion. Vision and pupillary light reflexes may be diminished.[83,85] The specific gait disturbances depend on the areas of the spinal cord involved. Signs of neurologic dysfunction may range from paraparesis to tetraplegia. The spinal reflexes range from hypertonia and hyperreflexia to hypotonia and hyporeflexia.[81–86] This diversity of signs is related to the variable location of lesions in the central nervous system (CNS).

Other clinical signs also are variable. In one study, affected goat kids remained afebrile, whereas in another study, 61% of affected animals had rectal temperatures ranging from 38.9° C to 41.3°C (103.6° F to 106.4°F).[81–86] Other signs that could be associated with systemic viral infection include enlarged joints, vague and shifting leg lameness, weight loss, and tachypnea without significant auscultatory abnormalities.

The major differential diagnostic considerations for the neurologic form of CAE include listeriosis or chlamydial and mycoplasmal infections. The CAE virus causes neurologic lesions in numerous regions of the CNS, whereas the lesions of listeriosis are generally restricted to the brainstem. Mycoplasmal infections typically affect kids ranging from 1 to 6 months of age, and affected animals develop polyserositis. They are systemically ill, and the joints are hot, grossly swollen, and painful. Goats with a mycoplasmal infection show extreme pain when the neck is passively flexed because of meningeal and vertebral articular inflammation. Fluid from the body cavities of goats with mycoplasmal infection has a high protein concentration and an increased number of polymorphonuclear cells.

35.2.2.2

Diagnosis

Previously, an AGID test was used for the diagnosis of CAE, but this has been superseded by ELISA and PCR tests.[88,89] The virus also may be cultured from infected tissue.[90] One study has reported an increase in total plasma protein and hypergammaglobulinemia in affected goats.[82] The results of other hematologic and blood chemistry analyses are normal. The changes in the CSF are characteristic only of a chronic granulomatous inflammation. Specific changes include an increased protein concentration and pleocytosis.[91] Cell counts in the CSF of affected goats range from 5 to 1800/dL, and the protein concentration ranges from 0 to 700 mg/dL.[80]

35.2.2.3

Pathogenesis

Being a member of the retrovirus group, the CAE virus contains RNA-dependent DNA polymerase. When inoculated into goats, the virus causes a chronic infection characterized by demyelinating encephalomyelitis, arthritis, and interstitial pneumonia. The pathologic changes resemble those of an autoimmune process and are probably caused by interactions between the host's immunologic responses, denatured myelin, and the virus.[92] Macroscopic pathologic changes in the CNS of naturally infected goats include cloudiness of the meninges and tan discoloration of the white matter.[81] Microscopic changes include disseminated perivascular accumulations of mononuclear cells, demyelination originating in the subependymal region, astrocytosis, and mononuclear leptomeningitis.[81,85,88,92,93] The inflammatory foci are predominantly composed of macrophages containing material that tests positive on periodic acid—Schiff (PAS) staining. Neuronophagia and neuronal necrosis are not seen.[93] Lesions are most severe in the periductular, periventricular, and submeningeal regions of the white matter. Spinal cord lesions are most frequently observed in the thoracolumbar segments.[80]

35.2.2.4

Treatment

No treatment is available for goats with leukoencephalomyelitis. Control measures are discussed in Chapter 38.

35.2.3 BORDER DISEASE (HAIRY SHAKER LAMBS; HYPOMYELOGENESIS CONGENITA)

35.2.3.1 Definition and Etiology

Border disease is a congenital infection of sheep and goats caused by a noncytopathic togavirus (genus *Pestivirus*).[94] The border disease agent is antigenically similar to the bovine viral diarrhea (BVD) and hog cholera viruses. Once introduced into a flock, the border disease virus causes a devastating syndrome characterized by abortion, infertility, and deformed lambs. The virus infects naive ewes during pregnancy and causes a variety of fetal malformations, including early embryonic death, abortion and stillbirth, and small, malformed lambs. A seroprevalence rate as high as 29% has been seen in a newly infected flock; however, lambs infected in utero become immunotolerant and remain viremic.[95] In an infected flock the incidence of fetal malformations and abortions declines over time because of the growing population of ewes with persistent active immunity. Adult sheep that become infected with the border disease virus develop an inapparent, short-lived viremia and become immune to reinfection.

35.2.3.2 Clinical Signs

The severity of clinical signs in affected lambs varies. Changes are most marked in newborn lambs infected in early gestation (before 50 days). The central nervous system (CNS), skin, and skeleton are the most seriously affected. The hairs of congenitally affected lambs are coarse, straight, and elongated and stand out from the body like a halo.[96] The coat is abnormally pigmented and may have a dark-gray appearance or hyperpigmented spots that are especially prominent over the top of the neck.[97] The combination of pigmentary abnormalities and long, coarse hair shafts gave rise to the descriptive term “steel wool coat.” Animals that survive shed the abnormal hairs at 9 to 12 weeks of age and replace them with normal hair fibers. Affected lambs also have a short, thickened body, shortened legs, smaller orbital size, and doming of the frontal bone.[98,99] Arthrogryposis occasionally may be seen. Some infected lambs show neurologic symptoms such as ataxia and uncontrollable tremors. The tremors are coarse, involve the trunk and head, and disappear when the animal is asleep.[100,101] The lambs often are alert and appetent but initially need assistance to stand and nurse. Some animals walk normally but hop on the rear limbs when forced to run. Over time the lambs become stronger but continue to show impaired locomotion for months. The CNS signs usually disappear by 20 weeks of age, but the animals appear stunted. Affected animals have greatly decreased viability compared with uninfected herdmates and may die suddenly without showing premonitory symptoms. Aside from neonatal death losses, economic burdens imposed by the viral infection include low birth weights, diminished weaning weights, lowered carcass quality, and infertility.[99,102]

Abortions that occur 9 to 106 days after inoculation are seen in 30% of experimentally infected sheep.[97,98,103] In field outbreaks the average gestational age of the aborted fetus is 63 days. Teratogenic effects are most often observed when lambs are infected at 50 to 90 days of gestation.[104] Fetal mummification occasionally may be seen.

The border disease virus is also pathogenic in goats.[105] As in sheep, inoculation of pregnant does results in fetal mummification and abortion. The spinal cords of infected kids are hypomyelinated, but the characteristic hair changes usually observed in sheep fetuses are not seen in goat kids.

The border disease virus has low pathogenicity for cattle. Abortions can be induced in cows inoculated with the virus at approximately 50 days of gestation, and affected calves have cerebral cavitations.[106] The condition is not recognized as naturally transmitted to cows.

35.2.3.3

Diagnosis

Identification of the viral antigens in tissues using fluorescent antibody tests is the most accurate method of diagnosing border disease. Tissues that most consistently contain viral antigens are those of the abomasum, pancreas, kidneys, thyroid, and testicles.[107,108] Serodiagnostic methods, including serum neutralization (SN), AGID, and complement fixation tests, have been developed.[109] In most cases the BVD virus has been used as the indicator antigen. Serodiagnosis of infected lambs is difficult because the lambs tend to be immunotolerant and therefore do not develop strong serologic responses. Sheep infected as adults develop SN titers ranging from 1:20 to 1:320, whereas the SN titers of animals with congenital infections are consistently below 1:10.[103] The presence of viral antibodies in the CSF suggests border disease virus infection.

35.2.3.4

Pathophysiology

Hypomyelination probably is caused by a combination of virus-induced degeneration of the oligodendroglial cells (dysmyelinogenesis), persistent viral infection, and diminished secretion of the thyroid hormones L-3,3′, 5′-triiodothyronine and thyroxine.[110] A deficiency of these hormones probably results in a lowered concentration of 2′,3′-cyclic nucleotide-3′-phosphodiesterase, which contributes to the hypomyelination. The diminished production of thyroid hormones is thought to be related to direct inhibition of the thyroid gland, because the pituitary activity of these lambs appears to be normal. Hypomyelination appears at approximately the same time as specific antiviral delayed-type hypersensitivity, indicating that an immunopathologic event may be partly responsible. Morphometric measurements of the spinal cords of lambs infected in utero show a permanent reduction of both white and gray matter in a cross-sectional area as a result of the decreased myelin content.[111] Depressed blastogenic activity of lymphocytes, a decrease in T4 helper cell function, and an increase in T4 suppressor cell function have been demonstrated in affected lambs between 4 and 7 months of age, indicating a viral immunosuppression.[112–114] Such immunosuppressed lambs succumb to parasitism, diarrhea, and bronchopneumonia.

35.2.3.5

Epidemiology

Border disease is transmitted both vertically and horizontally.[112,115] The agent can efficiently infect sheep through the intact mucous membranes. The major reservoir in infected herds is the asymptomatic, congenitally infected seronegative animal.[95,116] Sheep exposed to the virus as adults develop antibody responses and are able to clear the infections within weeks. Asymptomatically infected animals may shed the virus through the placenta, infected offspring, saliva, respiratory secretions, urine, or feces.[103,112] In one seroepidemiologic study of infected ewes in the western United States, lambs were more often seropositive than ewes.[95] A large percentage of the seropositive lambs were born to seronegative ewes, indicating the presence of a large amount of virus cycling from asymptomatic carriers. Strain-related differences appear to exist in viral pathogenicity.[117]

35.2.3.6 Necropsy Findings

The macroscopic changes associated with border disease virus infection are hydranencephaly, porencephaly, microcephaly, cerebellar hypoplasia, abnormal curvature of the ribs, brachygnathia, doming of the frontal bones of the skull, narrowing of the distance between the orbits, a decrease in orbital size, shortening of the crown-to-rump and diaphyseal lengths, retention of secondary hair fibers, and abnormal skin pigmentation.

Microscopic changes in lambs with congenital infection include hypomyelinogenesis and hypercellularity of the white matter with abnormal-appearing glial cells.[118] The CNS shows dysmyelinogenesis, secondary demyelination, and a nodular periarteritis. Viral antigen can be demonstrated in the adventitia of the CNS arterioles.[110] The microscopic lesions of the placenta include endothelial swelling, thrombotic occlusion of the vessels, and fibrinonecrotic cellular debris in the fetomaternal space.[118]

977 978

35.2.3.7 Treatment and Control

In herd situations, blood cultures and examination of skin biopsies by fluorescent antibody tests should be performed concurrently to identify carriers.[106] The SN test is not a reliable indicator of infection. Noninfected pregnant sheep should be kept separated from others in the flock for the first 60 days of gestation to ensure that in utero infections do not occur.

35.2.4 ENCEPHALITIC INFECTIOUS BOVINE RHINOTRACHEITIS VIRUS INFECTION

35.2.4.1 Clinical Signs

Two herpesviruses, bovine herpesvirus type 1 (BoHV-1) and type 5 (BoHV-5), have been associated with encephalitis in cattle.[119] BoHV-1 infection typically results in an acute upper respiratory tract disease characterized by fibrinonecrotic white plaques of the nasal, pharyngeal, and tracheal mucosa and abortions (see Chapter 31). Other clinical conditions associated with infectious bovine rhinotracheitis (IBR) infection include epizootic conjunctivitis (Chapter 39) and infectious balanoposthitis or vulvovaginitis (Chapter 43). Infection with BoHV-5, in contrast, usually results in meningoencephalitis with few or no respiratory signs. BoHV-1 infections also can result in meningoencephalitis, but much less frequently. The clinical signs of this encephalitis include depression, mild nasal and ocular discharge, conscious proprioceptive deficits, head pressing, aimless circling, bellowing, salivation, bruxism, paralysis of the tongue, head tilt, nystagmus, convulsions, blindness, coma, and death.[120,121] The seizure activity is characterized by a tonic-clonic convulsion with violent spasms or tremors of the head, with all four legs flexed and the head in opisthotonos.[120,121] Rectal temperatures of 41° C to 42°C (106° F and 107°F) have been reported.[122] The case-fatality rate of encephalitic IBR is almost 100%; however, recovery occurs in rare case. In experimental infection, signs develop 1 to 2 weeks after infection.

Differential diagnoses for encephalitic herpesvirus infections in cattle include almost all encephalitic, encephalopathic, and neurotoxic diseases of cattle, including rabies, polioencephalomalacia, salt poisoning, and lead toxicity. Accompanying respiratory disease raises the index of suspicion for herpesvirus. A rising serum neutralizing antibody titer in surviving animals can be used to confirm infection, although this does not distinguish between BoHV-1 and BoHV-5. Specific diagnosis is usually made at necropsy using a

number of modalities, including virus isolation, immunohistochemistry, and PCR.[123–125] Many of these tests do not distinguish between BoHV-1 and BoHV-5; more specific PCR and restriction fragment analysis techniques can differentiate between these two virus types.[126]

35.2.4.2

Epidemiology

Bovine herpesviruses cause disease in cattle worldwide, although the encephalitic form of infection is relatively rare in the United States. Epidemiologic factors that appear to favor dissemination of herpesviruses among cattle include a high stocking rate, repeated introduction of animals from diverse backgrounds, and mass weaning of calves at a time when the passively acquired anti-IBR antibodies are waning.[120] BoHV-1 may survive in the environment for up to a month; cooler ambient temperatures and higher humidity promote virus survival.[127] Calves less than 6 weeks old are most susceptible, but infection and resultant neurologic disease also have been described in adult cattle.[121,122,128–134] Animals that survive the disease become persistently infected; virus survives in the nasal and tracheal muscosa and the trigeminal ganglion. Reactivation and virus shedding may occur during periods of stress.[127–129,132] Although clinical disease caused by reactivation of latent virus is usually mild and may go unnoticed, shedding of virus during such episodes provides a source for infection of in-contact animals. The viruses grow in the nasal and pharyngeal mucosa. Brain involvement results from centripetal spread along the sensory neurons of the trigeminal and olfactory nerves.[132] Hematogenous dissemination to the brain is believed to be relatively unimportant.

35.2.4.3

Pathophysiology

Encephalitic IBR infections cause a nonsuppurative meningoencephalitis that is widely distributed in the gray matter of the brain. Pathologic abnormalities affect predominantly the forebrain, although all areas of the brain can be involved. Findings include marked perivascular cuffing with mononuclear cells, diffuse gliosis, neuronal degeneration and chromatolysis, hemorrhage, edema, necrosis, and neuronophagia. White matter lesions include myelitis with mononuclear cell infiltration and demyelination. Extensive lymphocytic meningoencephalitis is seen. Intranuclear inclusion bodies are rarely seen in bovine herpesvirus encephalitis. The virus usually can be isolated from brain homogenates of affected calves.

35.2.4.4

Treatment and Control

No adequate therapy exists for the encephalitogenic form of BHV-1 infection. Treatment is symptomatic and supportive and should include oral or intravenous fluid support, nonsteroidal antiinflammatory drugs (NSAIDs), antibiotics in animals with respiratory signs, and nursing care. Diazepam or phenobarbital may be used for seizure control when necessary (Table 35-3). Animals with severe clinical signs may be euthanized for humane reasons.

Vaccines that protect against BoHV-1 also may prevent BoHV-5 infection because of the close antigenic relationship between the two viruses.[128] Modified live intranasal vaccines may be most effective in preventing clinical disease and also can reduce shedding of virus by infected animals. In some European countries, eradication programs that employ testing and culling of infected animals have been successful in eliminating BoHV-1. Bovine herpesviruses can be spread through fomites and by aerosol transmission for up to 4 miles (6.4 km).[127] Strict biosecurity procedures are therefore essential to developing and maintaining virus-free herds.

35.2.5 BOVINE SPONGIFORM ENCEPHALOPATHY ("MAD COW" DISEASE)

CHRISTINE F. BERTHELIN-BAKER

35.2.5.1 Definition and Etiology

Bovine spongiform encephalopathy (BSE) is a transmissible spongiform encephalopathy (TSE) of cattle that was first described in 1987 in Great Britain (GB).[135] The TSEs are a group of slowly progressing, invariably fatal neurodegenerative diseases that can affect humans and animals. They are also called "prion diseases" because of the accumulation of prion in the central nervous system (CNS). Since the "prion hypothesis" was first formulated in 1982 by Stanley Prusiner, prions have been widely accepted as the etiologic infectious agents of the TSEs.[136] The prion is an isoform (PrPSc) of the normal prion protein (PrPc), a host-encoded membrane protein that does not carry any nucleic acid. PrPSc replicates by inducing a posttranslational conformational change in the normal protein PrPc to form the abnormal prion PrPSc.[136–138]

978

979

Table 35-3 Recommended Drug Dosages for Treatment of Cerebrocortical Disease

	Dose	Route	Frequency
ANTICONVULSANT DRUGS			
Valium	0.01–0.4 mg/kg	IV or IM	Twice daily or as needed
Pentobarbital sodium	2–10 mg/kg	IV	Three times daily
Phenobarbital	Loading dose 20 mg/kg	IV	One time
	Maintenance dosage 1–4 mg/kg	IV, PO, or IM	Divided twice daily
ANTIINFLAMMATORY OR ANTIEDEMA DRUGS			
Methylprednisolone	1–30 mg/kg	IV	One time
Dexamethasone	1–4 mg/kg	IV or IM	Twice daily
Mannitol	0.25–0.5 g/kg 20% solution	IV	Twice daily
Furosemide	1 mg/kg	IV, IM, or SC	Twice daily
Flunixin meglumine*	1 mg/kg	IV or IM	Twice daily
Phenylbutazone†	2–4 mg/kg	IV or PO	Twice daily
Dimethyl sulfoxide (DMSO)	1–2 g/kg	IV	Twice daily
Acetylsalicylic acid (aspirin)	7–10 g/500 kg	PO	Twice daily

IM, Intramuscular; *IV,* intravenous; *PO,* oral; *SC,* subcutaneous.

*	Monitor for signs of gastric or abomasal bleeding (fecal occult blood).
†	An initial loading dose of 10 to 20 mg/kg, followed by 2.5 to 5 mg/kg daily to every other day thereafter has been recommended for cattle. Because of the prolonged plasma half-life in ruminants, serial administration of the drug should be accompanied by careful monitoring of renal function and gastrointestinal bleeding.

35.2.5.2

Clinical Signs

Video clips of various clinical signs of BSE are available on the Internet.[139] As with all TSEs, BSE has a long incubation phase. It occurs mostly in 4- to 6-year-old cattle (age range, 20 months to 18 years). The clinical signs of BSE are usually insidious in onset.[140,141] They may be precipitated by stressful situations such as transportation, concurrent illnesses, or states of increased metabolic consumption, such as late pregnancy and parturition.

The detection of clinical signs of BSE and the array of clinical signs reported are influenced by how closely the cattle are being observed and the handlers' awareness of the insidious and nonspecific nature of the clinical signs. Subtle early behavioral changes are unlikely to be observed in large herds. Cattle may become apprehensive, stay apart from their herdmates, and become fearful of their handlers. As the disease progresses, cattle often become extremely excitable, especially when restrained or placed in confined quarters or an unfamiliar environment. BSE cattle may refuse to move through previously familiar doorways and become impossible to restrain. Unprovoked aggression is less frequently seen. Hyperesthesia is most marked around the head and neck. A light touch on the hindlimbs may induce violent, “ballistic,” and often repetitive kicking, which may also be observed during milking. Animals may overreact, startle, or “panic” in response to sudden visual, tactile, or auditory stimuli. The startle reaction may be gauged by a hand test (punching fist abruptly toward the animal's head without touching it), flashlight test, a hand clap, or a loud metallic “bang.” Normal animals rarely startle in response to such stimuli, or they may startle once or twice when the stimulus is repeated. BSE cases will frequently startle in a violent and repeatable fashion, with no habituation to a repeated stimulus. In some cases the response may escalate to an extreme “aberrant” startle, with head shaking and seizure-like head bobbing, which may be followed by violent turning, running around, and falling.[139]

Other possible clinical signs of BSE include ptyalism, increased head rubbing, muscle fasciculations, and excessive vocalization. Other behaviors seen in BSE may include frequent and repetitive head tossing, licking of the nostrils, yawning, flehmen, head tossing and head butting, and restlessness.[139,142] A relative bradycardia (≤60 beats/min) may be observed in animals when a tachycardia is expected because of their hyperexcited state. Affected animals often lose weight and have reduced milk output. Ataxia and tremors are seen in more advanced cases. Tremors most often involve the head and neck and may become generalized, especially with exercise. Ataxia is most marked on turns, when going over steps, or on uneven terrain; it may also be accentuated with exercise. BSE animals may become recumbent and unable to feed if the disease is left to run its course. Recumbency may also be triggered by an intercurrent illness or an injury during a fall. The clinical signs of BSE may be more difficult to recognize in animals that have become recumbent than in less advanced cases,[143] and systematic targeted surveys of “fallen stock” have allowed for the detection of previously unsuspected cases of BSE in various countries.[144]

35.2.5.3

Pathophysiology

The exact function of the prion protein is unknown, as are the mechanisms of neurodegeneration and CNS dysfunction in TSEs.

The presence of BSE infectivity in extraneural tissues has not been identified in natural BSE cases. In pathogenesis studies of cattle orally inoculated with BSE, infectivity was detected during the incubation period in the distal ileum from 6 months after challenge and in the CNS from 32 months after challenge (clinical signs first observed at 36 months).[145] Similar studies in sheep revealed infectivity within Peyer's patches by 4 months after experimental inoculation and in a wide range of tissues, including the CNS, by 16 months after inoculation.[146] PrPSc was detected in lymphoid tissue (Peyer's patches) of the distal ileum and in the bone marrow during the clinical phase of the illness.[147] Mice bioassays were negative for infectivity of milk, placenta, tonsils, and lymph nodes from BSE-affected and incubating animals. However, the more sensitive cattle bioassay showed that tonsils do carry small amounts of infectivity.[148] The full results of cattle bioassay studies have not yet been published.

979

980

35.2.5.4

Epidemiology and Zoonotic Potential

BSE may have derived from feedstuffs containing rendered carcasses of scrapie-infected sheep, or it might have been a preexisting sporadic and rare disease unrecognized in the bovine population. The BSE epidemic was traced to the recycling of BSE-infected carcasses into cattle feed, which occurred mostly in the 1980s in the United Kingdom (UK).[149] Cattle in other countries were affected as a result of the importation of infected feedstuffs or cattle, followed by later recycling the agent in their own rendered ruminant feedstuffs.

Bovine spongiform encephalopathy has predominantly affected dairy cattle because of their longer lifespan and more intensive feeding and wider use of concentrate than beef cattle. From 1986 to August 2006, a total of 179,140 cases of BSE were confirmed in GB. These cases have been distributed among 35,411 farms, representing about 60% of the farms holding adult cattle.[150,151] The cattle cohorts born in 1986 to 1989 had the highest incidence of BSE cases, and the peak of the outbreak occurred in 1992, when 36,680 cases were detected through scanning of suspect clinical cases (passive surveillance) in GB. A sustained and sharp decrease in the number of cases has occurred each year since 1992. In 2005, only 39 BSE cases were detected through passive surveillance (of 186 animals investigated), and another 164 (of 547,366 cattle tested) were detected through active (targeted) surveillance programs in GB.[151] The decline in the GB epidemic is directly related to the successive bans on the feeding of ruminant-derived meat and bonemeal to cattle. The initial 1988 ban took effect in 1989 in the UK and has been tightened and refined since then. Similar bans have been adopted by many countries around the world. A map of countries that have reported home-born or imported cases of BSE and the number of cases reported each year is available and regularly updated on the website of the Office International des Epizooties (OIE).[152]

No clear genetic predisposition to BSE has been demonstrated in cattle, unlike for scrapie in sheep. Calves born from dams in the later stages of the incubation of BSE are at most 10% more likely to develop BSE than their herdmates. This may be a result of an unidentified genetic predisposition or a low degree of vertical transmission. Mathematical modeling of the rate of reduction in the number of BSE cases in response to the initial feed bans introduced in the UK showed that vertical and lateral transmission of BSE, if they do occur, do so at a very low rate that could not sustain an outbreak of BSE. At the turn of the century, mathematical

modeling experts had initially predicted that BSE would be eradicated from the UK by the year 2005.[150] This prediction is being revised, especially because a previously unrecognized BSE phenotype has been identified in Italy, France, and Germany.[153,154]

Since the onset of BSE epidemic, new TSEs have occurred in domestic cats, various exotic species, and humans.[151] Strain typing in mice showed that these new TSEs were caused by the BSE agent.[155,156] A new variant Creutzfeldt-Jakob disease (vCJD) was first identified in 1996 in the UK, where it has affected 162 people to date.[157] Other countries have detected vCJD cases (two in United States) in people who had lived in the UK between 1980 and 1996, when the strictest measures were enforced to prevent human infections. France, Italy, Republic of Ireland, The Netherlands, Portugal, Spain, and Saudi Arabia have detected vCJD cases in residents who never traveled to the UK. The emergence of vCJD has put worldwide emphasis on the prevention and detection of TSEs in animals. The route of infection of people by BSE has not been clearly traced, but it is generally accepted that the consumption of food that included cattle nervous system was the main cause of vCJD in people. Successive "Specified Risk Materials" bans have been enforced to prevent contamination of human food with nervous system from ruminant animals.

35.2.5.5

Diagnosis

No in vivo test is available for the diagnosis of BSE. Clinical suspicion can be confirmed only by postmortem examination. The diagnosis of BSE is based on microscopic brain examination or tests that identify prion in brain or spinal cord tissue.[135,153,154,158] Rapid prion tests include Western blot, paraffin-embedded tissue (PET) blot, and ELISAs.[159–162] Rapid tests have enabled the detection of BSE though surveillance in targeted at-risk populations, such as fallen cattle.

Histopathologically, BSE is characterized by neuronal degeneration and intraneuronal vacuolation in specific brain areas. The vacuolation is accompanied or preceded by the accumulation of PrPSc.[149,163,164] The uniformity of the pathology among affected cattle along the UK epidemic and in various other countries has generally supported the theory that all BSE cases were caused by a single strain of TSE agent, which has been defined by its specific BSE histopathologic phenotype.[149,164–167] Since 2004, atypical BSE cases have been described in Italy, France, and Germany.[153,154,168] Further studies are ongoing to determine whether these cases reflect the existence of a previously unidentified strain of BSE.

35.2.5.6

Differential Diagnosis

Nervous system diseases that could be confused with BSE include viral encephalopathies (pseudorabies, rabies, Borna encephalitis, bovine immunodeficiency virus encephalitis), listeriosis, polioencephalomalacia, lead poisoning, CNS parasitic migration, brain tumors and abscesses, and vitamin A deficiency. Hepatic encephalopathy and other metabolic imbalances may also be confused with BSE. Because of the insidious nature of BSE, affected cattle may appear to recover coincidentally with blanket therapy for suspected metabolic imbalances and later relapse. This must be kept in mind whenever therapy for metabolic imbalances initially appears to be successful but is followed by one or more relapses.

35.2.5.7

Treatment and Prognosis

BSE is always fatal, and no treatment is available.

35.2.5.8 Control

Various measures have been taken to protect public health by removing potentially infected animals and tissues from the food chain. The disposal of BSE-infected tissues and the sourcing of bovine tissues and body fluids for the preparation of medicinal products must take into account the extreme resistance of TSE agents. All TSE agents remain infectious after exposed to a wide range of inactivating treatments and environmental changes, such as autoclaving, rendering, storage for months to years, exposure to ultraviolet light, freezing, thawing, prolonged boiling, and incubation with formalin.[169–172] Because of the public health risk, the carcasses of animals suspected of having BSE should be incinerated.

In countries that have had an outbreak of BSE, the complete exclusion of ruminant tissues from ruminant feed has aided progress toward eradication of BSE, as previously noted. In the UK the initial feed ban of 1988 was found to be insufficient and was reinforced by successive measures. The 1996 ban on feeding mammalian meat and bonemeal to all farmed animals was introduced to prevent contamination of ruminant feed at feed mills and down the supply chain to the farm. Because of the long incubation period of BSE, there is a lag time in the effect of feed control measures, and the full effect of such measures can be assessed only when all animals born after a feed ban reach 4 to 8 years of age.

35.2.6 SCRAPIE

35.2.6.1 Definition and Etiology

Scrapie naturally affects sheep, goats, and mouflons. It is the oldest known TSE. It has affected sheep in various countries for more than 250 years. Strain typing in mice has demonstrated the existence of a variety of scrapie agents, none of which are identical to the agent of BSE.

35.2.6.2 Clinical Signs

Video clips of various clinical signs of scrapie are available on the web.[139] Most animals with scrapie are 1 to 5 years old. The clinical course varies but is typically slow and may last several months. Shepherds who work closely with their sheep can best recognize the early signs of scrapie. Early behavioral changes are often accompanied by weight loss. Scrapie cases may stay apart from the flock and become nervous and restless.[173] Pruritus of increasing intensity is a common feature; sheep may rub on fixed objects, scratch with their horns or hooves, and bite or lick at themselves excessively. The head, withers, flanks, back, rump, base of the tail, and lower limbs are typically affected, showing secondary wool loss, dermatitis, and skin infections or excoriations.[173,174] Head and face rubbing and shaking may also cause corneal chemosis or aural hematomas. When scratching the pruritic areas (mostly the back and rump), the animal may display a “scratch reflex” (or “nibble reflex”), which may include reflex nibbling, lip licking, and rhythmic head movements. This reflex is often but not always present in scrapie cases. It may also be observed in other CNS diseases and in pruritic skin diseases, especially ectoparasitism.

Other clinical signs of scrapie include bruxism (tooth grinding) and ptyalism. Less frequently, rumen fluid (cud) may leak through the nostrils or the mouth. Tremors may start with the head and generalize to the whole body. As the disease progresses, some sheep with scrapie may develop signs of apathy, exercise intolerance, and ataxia. The most severe and advanced cases may show convulsions, collapsing episodes, and

stupor. If scrapie is left to run its course, death may occur during a convulsion or as a result of starvation. The clinical signs of scrapie in goats are broadly similar to those in sheep.[174–178] Scrapie has been identified in fallen stock, especially in flocks that are not closely supervised.

35.2.6.3

Pathophysiology

The exact mechanism of CNS degeneration in TSEs has not been identified. The oral route is the most likely route of entry of the scrapie agent,[179,180] which probably enters the gastrointestinal (GI) tract and is transported to peripheral lymphoid tissue.[181,182] Follicular dendritic cells are infected early in the disease course, and there may be an interface between the lymphoreticular system and the nervous system.[183] Transport to the CNS likely occurs along the vagus nerve from the GI tract.[184] PrPSc has been identified by immunocytochemistry in the GI tract (in Peyer's patches and in autonomic plexuses) and in various lymphoid tissues of sheep with scrapie.[185,186] Replication of the agent takes place in lymphoid tissues, including the spleen, but circulating lymphoid cells do not appear to be involved in scrapie replication.[181,182,187]

35.2.6.4

Epidemiology

Scrapie occurs endemically in sheep flocks worldwide.[188–190] Sheep are the natural host of scrapie, but the infection can be maintained in goats that have no direct contact with sheep, indicating both lateral and vertical transmission of the agent in that species.[174,175,188,191] Scrapie cases occur sporadically in infected flocks. Only one or a few animals are affected at any given time. Outbreaks with up to 40% of animals affected in a flock have been linked to the use of infected vaccines[192] or to the introduction of scrapie by an infected animal in a previously uninfected and genetically sensitive flock. The route of natural infection is presumed to be oral. The route of excretion and the means of transfer of the agent between sheep are unknown.[179] Lambing time is known to be a particularly high-risk period for infection for the young. The contamination of pastures with infected placentas is likely to be an important reservoir of the infectious agent in nature.[173,193,194]

Although there is no known breed predisposition to scrapie, the genetic makeup of the host controls differences in susceptibility and resistance to scrapie in various breeds.[172,195,196] The molecular basis of this resistance is largely controlled by the PrP gene.[197] The gene responsible originally was thought to determine the incubation period of scrapie and was called *sip*. This gene is now known to be the prion protein gene. Polymorphisms at three codons of this gene appear to be the main determinants of the susceptibility of sheep to scrapie.[198,199] According to current evidence, the genotype $VV_{136}RR_{154}QQ_{171}$ (or $AA_{136}RR_{154}$ QQ_{171} in some breeds) is most susceptible, and the genotype $AA_{136}RR_{154}RR_{171}$ is totally resistant.[200] The potential relevance of other polymorphisms and other genetic factors is unknown. Selection of scrapie-resistant sheep flocks may be based on pedigree, phenotypic expression of the disease,[172] or genetic testing to select sheep of “resistant” PrP genotypes.[200] Studies are ongoing to determine whether “genetic resistance” may confer resistance to disease but not resistance to infection, in which case some genotypes of sheep could act as asymptomatic carriers of scrapie.[151]

35.2.6.5 Treatment and Prognosis

Scrapie is a fatal and irreversible disease for which there is no known treatment.

35.2.6.6 Diagnosis and Pathology

35.2.6.6.1 IN VIVO DIAGNOSTIC TESTS

Immunohistochemistry may show PrPSc in biopsies of tonsils or nictitating membranes, allowing for diagnosis of infection in live animals that are incubating or in the clinical phase of scrapie.[201–203] However, these tests may be negative in scrapie cases, and their interpretation requires a high degree of experience. Further research is in progress to increase the sensitivity of PrPSc tests. Newer tests also are being developed to detect PrPSc in blood and cerebrospinal fluid (CSF).[204–206]

35.2.6.6.2 DIFFERENTIAL DIAGNOSIS

Nervous system diseases that could be confused with scrapie include pseudorabies, rabies, Borna encephalitis, listeriosis, polioencephalomalacia, lead poisoning, parasitic migration in the CNS (coenurosis), brain tumors, brain abscess, maedi-visna virus infection, vitamin A deficiency, pregnancy toxemia, and other metabolic imbalances. When pruritus is the only clinical sign, skin diseases such as psoroptic and sarcoptic mange, ringworm, myiasis, pediculosis, and atopy may be considered as differential diagnoses. Because of the insidious nature of the illness, animals with early scrapie may initially appear to respond to blanket treatments. This must be kept in mind whenever specific therapy for another suspected illness appears initially to be successful but is followed by relapse. When therapy of an alternate condition fails, the final diagnosis must rely on detailed examination of appropriate postmortem samples.

35.2.6.6.3 POSTMORTEM DIAGNOSIS

Microscopic examination of the brain and spinal cord is the classic diagnostic method for scrapie. It is possible only when tissues are collected soon after death, before autolytic changes take place. Neuronal vacuolation and PrP deposits are found in specific brain nuclei.[207–212] In autolyzed tissues, PrPSc can be identified by immunohistochemistry testing, Western blot tests, or ELISA.[160,161,212–214] 981 982

35.2.6.7 Control

Because there is no effective treatment for scrapie, control measures designed to prevent the spread of the disease are especially important. Scrapie is a reportable disease. Eradication measures vary from country to country.[149,215] Animals suspected of having scrapie are slaughtered and destroyed. Contaminated pastures or paddocks may be left empty of livestock, but the scrapie agent is unlikely to be inactivated in the environment. Contaminated stalls, corrals, and sheds should be disinfected with sodium hypochlorite diluted at 4% available chlorine. In the United States and Canada, scrapie-affected and related animals are destroyed and their flocks quarantined.[215] Lines of sheep genetically resistant to the development of clinical scrapie

have been selected.[216] These sheep do not develop the clinical signs of scrapie, but they may have a chronic asymptomatic infection that could spread to sheep of susceptible genotypes.[172,216,217]

35.2.6.8 PUBLIC HEALTH CONSIDERATIONS

Although scrapie has been endemic in various areas of the world for more than two and a half centuries, epidemiologic studies have not shown any correlation between the incidence of Creutzfeldt-Jakob disease in humans and that of scrapie in sheep.[218] It is nevertheless wise to take precautions to minimize the potential for human exposure to scrapie because some sheep could have been infected by BSE, which would be identical to scrapie in any infected flock.[219] In a study of BSE orally transmitted to sheep, the clinical signs of BSE were identical to those of scrapie.[220]

35.2.7 MURRURUNDI DISEASE AND SEGMENTAL AXONOPATHY OF MERINO SHEEP

Murrurundi disease occurs in the sheep of New South Wales.[221] The condition is a spongiform encephalopathy that has some similarities to scrapie, humpyback, and Coonabarabran disease; however, the three conditions are pathologically differentiable. Murrurundi disease occurs in sheep between 1 and 5 years of age. The initial clinical sign is posterior paraparesis, with progression to paraplegia after several months. No wool breakage occurs in affected animals. Microscopic changes include multiple cytoplasmic vacuolation of the neurons and chromatolysis of Nissl substance. The cause of the disease is unknown.

A similar condition has been described in Merino sheep that developed progressive paraparesis between 1 and 4 years of age.[222] Axonal spheroids within white matter tracts of both the brain and spinal cord were the main pathologic feature of this disease.

35.2.8 HUMPYBACK DISEASE

Humpyback disease affects Merino wethers of Australia. The neurologic signs of the condition are not usually observed until the sheep are gathered for shearing. The affected animals lag behind the flock and show posterior ataxia. They may fall or stand quietly with the head lowered and the back arched; thus the common name of the condition. The clinical signs include rear limb ataxia, stiffness of the rear limbs, knuckling of the fetlocks, arched back, and recumbency. After resting for several minutes, affected sheep arise and travel for a short distance but soon are immobilized again. Eventually the disease leads to recumbency and death. Affected animals worsen over several years.[223] Wallerian degeneration of the spinal cord is the major pathologic change seen in affected sheep; however, the severity of microscopic changes do not correlate well with the clinical signs. The cause of the condition is unknown.[224,225]

35.2.9 EQUINE HERPES MYELOENCEPHALOPATHY

JOHN W. SCHLIPF

MARY O. SMITH

Eight types of herpesvirus affect horses, donkeys, and possibly other equids.[226,227] Of these, equine herpesvirus type 1 (EHV-1) is clinically important because it sometimes is associated with neurologic disease.[226] EHV-1 is

more frequently associated with reproductive disorders, neonatal diseases, and respiratory disease.[226,228,229] Equine herpesvirus type 4 is primarily associated with respiratory disease and is discussed extensively in Chapter 31.[228] Equine herpes myeloencephalopathy results from ischemic damage to the spinal cord, not from viral infection of neurons.[226] Single individuals may be affected, but outbreaks involving several horses in the same environment have been reported; such involvement of multiple animals raises the index for suspicion of EHV-1.[230–232]

35.2.9.1

Clinical Signs

Acute onset of ataxia and tetraparesis of variable severity most often characterizes the neurologic form of EHV-1.[229,233] Signs usually appear between 6 and 10 days after infection.[229] The severity of clinical signs can range from subtle neurologic deficits to complete recumbency. Other signs also may be seen, including nasal discharge, limb edema, colic, ocular lesions, and anorexia.[226,228–231,233] The animal may be febrile at presentation, but most are normothermic.[226,229] Pyrexia is the most consistent premonitory sign before the onset of neurologic disease, although not all pyrexic horses will develop myeloencephalopathy.[232,234] Coughing and nasal discharge sometimes accompany the neurologic deficits or may have been present in the preceding 2 weeks.[231]

The neurologic signs reflect damage to the white matter of the spinal cord and include ataxia, paresis, conscious proprioceptive deficits, urinary incontinence, flaccid tail and anal tone, and diminished perineal sensation.[226,229,233] Hindlimbs are more severely affected, and deficits usually are symmetric. Bladder atony and dysuria frequently occur, and the associated dribbling of urine leads to secondary perineal scalding. Anal sphincter tone also is diminished, which may result in a distended rectum.

Cranial nerve deficits, including seizures, blindness, and vestibular signs, have been reported with EHV-1 infection.[231] Ocular lesions also may be present, such as mydriasis, hypopyon, uveitis, and optic neuritis.[226,229,235,236]

The clinical signs typically stabilize within 48 hours, although progression varies. Some patients continue to deteriorate and eventually die or are euthanized. Most horses begin to improve within the first 5 to 7 days and ultimately make a full recovery, although the recovery may take months. A patient that does not become recumbent has a much better prognosis.[233,235]

35.2.9.2

Diagnosis

A tentative diagnosis can be made based on characteristic neurologic signs, the history, and supporting findings on the physical examination. A cerebrospinal fluid (CSF) analysis that shows an increase in protein and a normal or slightly increased nucleated cell count (albuminocytologic dissociation) is the classic CSF change seen with EHV-1 infection.[226,229,237] Cerebrospinal xanthochromia may also be seen.[233] The protein level may be normal, which does not necessarily rule out EHV-1. Occasionally, early in the disease the CSF may be normal or may show only mild abnormalities; CSF protein concentration in the normal range does not rule out EHV-1.[226] 982 983

A fourfold or greater increase between acute and convalescent virus neutralizing (VN) antibody titers is consistent with a diagnosis of EHV-1 infection.[237] VN titers usually are the easiest and most economic to

perform. Because they rise quite rapidly and reach a level much higher with natural infection compared with vaccination, a fourfold rise in the VN titer may not be seen, especially if collection of the acute sample was delayed.[226,235] A single titer of 1:256 or higher is highly suggestive of recent infection.[229,237] The titer of VN antibodies does not correlate with protection against infection or with reduced viremia.[238] Complement fixation (CF) titers decline quite rapidly after infection, requiring sample collection early in the course of the disease. A titer higher than 1:16 is consistent with recent infection.[237] It is important to know which assay the diagnostic laboratory uses, because interpretation of the results differs depending on the test performed.

Viral isolation attempts from the buffy coat of an ethylenediamine tetraacetic acid (EDTA) tube and nasopharyngeal swabs may yield a positive result for EHV-1 for approximately 10 to12 days after infection.[226] It is critical that samples be handled appropriately and transported to the laboratory as soon as possible. A viral transport medium is necessary and should be available from the diagnostic laboratory. Viral isolation from the CSF is unrewarding because there does not appear to be direct viral infection of neurons.[233]

35.2.9.3

Pathophysiology

An apparent immune complex vasculitis and thrombosis in arterioles of the spinal cord lead to segmental spinal cord ischemia. Although the lesions are characteristic of a type III (Arthus) hypersensitivity, an immune-mediated pathogenesis has not been conclusively demonstrated.[229] However, the theory of an immune-mediated pathogenesis is supported by the finding that horses vaccinated within the previous 12 months were shown to be 9 to 14 times more likely to develop the neurologic form of EHV-1 infection.[229] The vasculitis may be the result of viral infection of the CNS endothelium by circulating infected leukocytes.[233] The CNS vascular endothelium appears to be the primary site for infection, and the development of neurologic disease may depend in part on the endotheliotropism of the virus. Viral replication within neural tissue has not been definitively demonstrated.[226,229]

35.2.9.4

Epidemiology

Herpesvirus infection is enzootic in the horse population. Infection usually occurs through the respiratory or intestinal epithelium after the animal comes in contact with the virus in fluids from an abortion or in ocular, nasal, or respiratory tract secretions.[229,235] Most horses become infected before 1 year of age. As with most herpesvirus infections, the virus is capable of evading the horse's immune system and can develop latency.[229,235,239] Sites considered likely for latency are the lymphoid tissue and the trigeminal ganglion.[239,240]

Equine herpes myeloencephalopathy is rare, but cases have been reported worldwide.[229] The existence of a neurovirulent form of the virus has been suspected, but the differences in the strains isolated from neurologic syndromes are not significant enough to warrant additional classification.[226] However, equine herpes myeloencephalopathy outbreaks have been reported, lending support to the idea of a neurovirulent form.[230,233,235] During outbreaks, the virus appears to be spread readily, and both morbidity and mortality can be high.[234]

Animals of any age or gender are susceptible; pregnant or lactating mares are most often affected.[226,229] Risk factors for the development of neurologic signs include female gender, older age, and fever. A higher prevalence of neurologic disease was found in standardbred, Hispanic breeds, and draft horses in one study

of multiple outbreaks of herpesvirus myeloencephalopathy.[229] Foals are rarely affected with the neurologic form of EHV-1 infection. There appears to be some seasonal variation because more cases are seen during the spring and winter months.[232] Stress-associated recrudescence of latent infections and shedding without clinical signs are important in the development of equine herpes myeloencephalopathy in a closed population. The virus may be shed for 3 weeks or longer after infection. A morbidity rate of up to 90% and a mortality rate of up to 40% have been reported.[229,233] There are no reports of equine herpes myeloencephalopathy associated with any modified live virus vaccine currently approved for use in horses.[175] Frequent vaccination (up to four times a year) may render animals more susceptible to neurologic manifestation of EHV-1 infection.[234]

35.2.9.5

Necropsy Findings

Gross and histologic lesions are not always limited to the CNS.[226,233] Ocular lesions have been reported, including hypopyon, iritis, and chorioretinitis. Cystitis and scrotal edema may be present.[226,229] Focal areas of hemorrhage may be found throughout the brain and spinal cord parenchyma and meninges. Vasculitis of the small arteries and veins of the spinal cord white matter and of the gray and white matter of the brain results in ischemic lesions in the CNS.[241,242] Equine herpesvirus is infrequently isolated from the CNS during a postmortem examination.[230,237] Polymerase chain reaction (PCR) and direct immunofluorescence assay in situ can be performed on CNS tissues obtained postmortem to confirm the presence of the virus.[230]

35.2.9.6

Treatment

Supportive care is the most important aspect of treatment for equine herpes myeloencephalopathy.[226,229,233,237] Measures include bladder decompression twice a day for horses with bladder atony and urinary incontinence, evacuation of the rectum, enteral or parenteral nutritional support, and administration of intravenous or oral fluids. The horse may require support in a sling.

Administration of antiinflammatory drugs soon after the onset of neurologic signs may be beneficial. Corticosteroids have been used because of the possible immune-mediated pathogenesis, but no objective data are available evaluating the efficacy of this treatment. Dexamethasone (0.05 to 0.1 mg/kg IV) can be given every 12 to 24 hours for 3 to 5 days, with the dosage then tapered for 1 to 3 days.[237] The possibility of viral reactivation is unlikely at the recommended dosage.[229] Dimethyl sulfoxide (DMSO; 0.25 to 0.1 mg/kg by slow IV infusion) every 12 to 24 hours is routinely used when treating neurologic disease, although its efficacy has not been documented.[226]

Use of antibiotics should be considered if the horse is recumbent or has urinary tract involvement, or if respiratory tract signs are present. Antiviral agents, particularly acyclovir, have been recommended based on their use in humans for herpes simplex virus encephalitis. There is insufficient evidence to recommend the use of antiviral agents for EHV-1 infection in horses.[237]

35.2.9.7

Prevention

Currently, no prophylactic measures for or methods of preventing equine herpes myeloencephalopathy are available. The vaccines currently used to prevent EHV-1 respiratory and abortion syndromes do not claim to

prevent equine herpes myeloencephalopathy. Findings in vaccinated horses naturally exposed to EHV-1 during disease outbreaks are mixed regarding protection against myeloencephalopathy.[232,238] Vaccination may reduce the incidence of the other EHV-1—related diseases and thereby reduce exposure to the virus and the risk of developing equine herpes myeloencephalopathy. A recent study concluded that modified live virus vaccine provided significantly better protection against EHV-1 myeloencephalopathy than a killed vaccine,[238] although the duration and robustness of such protection are not yet clear. Vaccination in the face of an outbreak is controversial[226]; viremia may be reduced or prevented as a result of vaccination, but an increase in antibody levels may be partly responsible for, or may play a role in the development of, the neurologic form.

Management practices may reduce the risk of introducing or disseminating EHV-1 infection. Such practices include isolating all new arrivals for at least 3 weeks and maintaining distinct herd groups based on age, gender, and occupation. Pregnant broodmares should be kept apart from the general population as much as possible. Minimizing stress may reduce the likelihood of recrudescence of a latent infection.

35.2.10 PSEUDORABIES (AUJESZKY'S DISEASE, MAD ITCH, BULBAR PARALYSIS)

CHRISTINE BERTHELIN-BAKER

LISLE W. GEORGE

35.2.10.1 Definition and Etiology

Pseudorabies is caused by an encapsulated DNA virus, suid herpesvirus type 1 (Su-HV1), a member of the genus *Varicellovirus*, subfamily Alphaherpesvirinae, family Herpesviridae.[243,244] This virus is able to infect the CNS and other organs (e.g., respiratory tract) of virtually all mammals except humans and most primates. Domestic and feral swine are the natural hosts and may become latent carriers. The virus can also infect cattle, sheep, cats, dogs, and goats as well as wildlife (e.g., raccoons, opossums, skunks, rodents) and rarely, horses.[245–248] In domestic and wild ruminants, pseudorabies is an acute and usually fatal encephalitis.

35.2.10.2 Clinical Signs

The incubation period ranges from 90 to 156 hours, and the illness may last 8 to 72 hours, although some affected animals have been found dead without any observed clinical signs.[249,250] The initial clinical sign is usually a manifestation of paresthesia, with acute and severe pruritus inducing self-trauma, dermal abrasions, swelling, and alopecia.[249] Other signs may include fever, bellowing, bloat, feet stamping, excessive salivation, chewing of the tongue, ataxia, circling, nystagmus, and strabismus.[251–253] Aggression may be seen, but most affected animals become depressed. As the disease progresses, there may be twitching, hyperesthesia, tenesmus, spasmodic kicking, excessive licking of the nostrils, continuous mastication, sweating, vocalization, semicoma, coma, convulsions, opisthotonos, hyperpnea, tachypnea, and slow irregular respiration.[254] The clinical signs of pseudorabies in cattle closely resemble those of rabies, polioencephalomalacia, salt poisoning, meningitis, lead poisoning, hypomagnesemia, and enterotoxemia.

35.2.10.3

Clinical Pathology

The Aujeszky's disease virus (ADV) can be isolated from the pharyngeal or nasal secretions of affected animals and can be easily cultured from infected nervous tissues. Strains of ADV are antigenically distinct from other herpesviruses but share common antigens with the infectious bovine rhinotracheitis (IBR) virus. Heterospecific antibodies to the IBR virus may cross-neutralize the pseudorabies virus and confound serologic tests. For virus culture, tissues should be collected from sensory ganglia or the sensory parts of the spinal cord. Segments serving the pruritic sites should be collected preferentially because these areas contain the highest concentration of virus.

35.2.10.4

Pathophysiology

Ruminants are susceptible to pseudorabies infection after intradermal, subcutaneous, intranasal, or oral exposure to the virus. After subcutaneous, oral, or nasal infection, the virus spreads centripetally to the CNS by axonoplasmic transport. During the acute infection the virus may be present in the nasal mucosa, secretions, and saliva.

35.2.10.5

Epidemiology

Aujeszky's disease has a worldwide distribution and, although cases occur only sporadically, is an economically important disease because of the regulatory quarantine and other restrictions imposed on animals from affected herds (it is a reportable disease). Outbreaks have occurred in cattle in the United States, Europe, Australia, New Zealand, Latin America, and South America. Until recently, Aujeszky's disease was endemic in the United States, but it now has been successfully eradicated from domesticated swine. As of December 2006, all states are classified as free of pseudorabies in domesticated swine (OIE status V), although ADV remains present in feral pigs in parts of the United States.

The viral infection in cattle is perpetuated partly by the occurrence of latent infections in pigs, which can be recrudesced by stressful conditions.[255] Occasional spillover of the virus from swine into ruminants occurs because of the proximity of the two species in many livestock operations.[250,256] The natural routes of transmission include nose to nose, fecal oral, and venereal.[245,257] Indirect transmission usually occurs by inhalation of aerosolized virus. The virus may travel via aerosols up to 2 km (1.2 miles) in certain weather conditions and may survive up to 7 hours in nonchlorinated well water; for 2 days in anaerobic lagoon effluent and in green grass, soil, feces, and shelled corn; for 3 days in nasal washings on plastic and pelleted hog feed; and for 4 days in straw bedding. It is inactivated by drying, sunlight, and high temperatures (≥37°C). Dead-end hosts, such as dogs, cats, and wildlife, can transmit the virus between farms, but aside from feral swine, these animals survive only 2 to 3 days after becoming infected. Sheep have also been infected by modified live virus vaccines targeted for use in swine.[258,259]

Latency of the viral infection in ruminants is not an important mechanism for perpetuation of an outbreak; most animals die within 48 hours of disease onset and may shed ADV in their saliva, oral secretions, and mucous membranes for only up to 6 days after infection, and direct spread of the virus between infected and uninfected cattle is unlikely.[256] Wild mammals such as raccoons may play a role in pseudorabies survival and transmission; rats, however, develop transient infections and do not appear to transmit or perpetuate the virus.[260–262] The pseudorabies virus may survive in contaminated meat products for up to 7 weeks. The role

of this prolonged survival in perpetuating outbreaks in ruminants is unknown. Differences in virus pathogenicity for cattle have been correlated with the type of syncytium formation in tissue cultures.[262] The role of these strain differences in the perpetuation and dissemination of the disease is unclear.

35.2.10.6 Necropsy Findings

The macroscopic changes that occur in animals infected with the pseudorabies virus are alopecia, edema, and hemorrhage at the pruritic site. The neuropathologic changes include perivascular cuffing, interfascicular edema, nonsuppurative encephalitis, gliosis, neuronal degeneration, and eosinophilic intranuclear (Cowdry type A) inclusion bodies. The lesions are most pronounced in the dorsal nerve rootlets and the dorsal horn.

35.2.10.7 Treatment

There is no treatment for pseudorabies, which is usually fatal in livestock, although rare recoveries have been reported.[252]

35.2.10.8 Prevention

The most effective method of preventing pseudorabies virus infection in ruminants is eliminating their exposure to swine. Contaminated pens can be disinfected with 10% sodium hypochlorite solution, quaternary ammonium compounds, tamed iodine, or phenolic compounds.[263] At least 5 minutes of contact time should be allowed before the disinfectant is rinsed from the contaminated surfaces. Fumigation with formaldehyde for 6 hours effectively kills the virus, as does 360 minutes of contact with ultraviolet light.

35.2.11 ALPHAVIRUSES

MAUREEN LONG

E. PAUL GIBBS

Vaccination has reduced the size and number of outbreaks of eastern equine encephalitis (EEE), western equine encephalitis (WEE), and Venezuelan equine encephalitis (VEE) in horses from thousands of cases in the United States to several hundred annually.[264] Nonetheless, these diseases are important because of the resulting mortality or permanent deficits after infection in horses, and because horses are in important part of the surveillance network for arboviruses that also affect humans. Reporting of infection with EEE and WEE in horses is a requirement of licensed veterinarians in most U.S. states, and VEE is considered a foreign animal disease and also has federal reporting requirements.

35.2.11.1 Etiology

Togaviruses are single-stranded, linear, positive-sense RNA viruses with an envelope that makes them susceptible to drying and ultraviolet light. EEE, WEE, and VEE viruses are the most frequently isolated togaviruses from epidemics of encephalitis in horses and humans in the Western Hemisphere.[265] The first recorded epidemic of EEE in horses occurred in Massachusetts in 1831; the virus was first isolated from a

horse in 1933.[265] It was soon determined that epidemics of encephalitis in horses in North America were caused by different alphaviruses with regional geographic biases.[266,267]

The virus is composed of a nucleocapsid within the envelope that has icosahedral symmetry consisting of peplomers arranged as trimers.[265] Viral species are differentiated by hemagglutination inhibition (HI) activity and neutralizing specificity.[267–269] The common group-specific antigenic determinants are still mainly defined by serologic techniques, such as fluorescent antibody, complement fixation, and ELISA.[270–274] Genetic sequencing has application in molecular epidemiology.[275–277]

For WEE virus, WEEV and Highlands J virus (HJV) constitute the two main subgroups.[278–281] WEEV predominates west of the Mississippi River, whereas HJV is primarily detected east of the Mississippi.[282,283] Both these viruses are capable of causing encephalitis in horses, with HJV likely less pathogenic for mammals.[282,283] Other subtypes of WEE virus have been identified in the United States, and most WEE infections in western states are likely the result of infection with one of the several antigenic variants of the actual WEE subtype, although minimal disease has been reported in humans and horses in the last decade.

The organization of VEE is much more complex. Six distinct subtypes (I through VI) and numerous varieties of viruses (designated by letter) within these subtypes are classified within the VEE virus complex.[284–288] The “epidemic types” of VEE virus (types IAB, IC, and IE) are responsible for the large outbreaks of encephalitis in horses in the Western Hemisphere in the past 20 years.[289,290] “Endemic types” of VEE virus are considered to be of low pathogenicity for equids under most circumstances.[291,292] These include type ID and IF variants from Central America and Brazil, respectively; type II (Everglades) virus found in Florida; three known variants of type III (Mucambo) virus; type IV (Pixuna) virus; type V (Cabassou) virus; and type VI virus.

35.2.11.2 Epidemiology

The classic life cycle of equine alphaviruses involves transmission between birds or rodents and mosquitoes.[274] In some cases, other domestic and wild animal species, especially species exotic to North America such as the emu, have been affected during these outbreaks.[293] Understanding the antigenic and genetic relationships among the viruses in the WEE complex has proved more challenging than for the viruses in the EEE and VEE virus complexes. WEE virus is a member of the WEE antigenic complex that includes several Old World viruses in addition to the New World viruses previously described. Phylogenetic analyses of isolates from North and South America indicate that regional WEE lineages appear to evolve independently for several years to a few decades (e.g., genotypes in South America are apparently absent from North America).[283,294–296] However, relatively homogenous genotypes of WEE are dispersed across both North America and South America. This contrasts with EEE and VEE viruses, in which certain virus genotypes appear to be restricted to either North America or South America. WEE virus has been reported in several countries in South America (Argentina, Guyana, Ecuador, Brazil, and Uruguay), but only in Argentina has it been associated with human disease and significant epidemics in horses.[281,297–299]

35.2.11.2.1 EASTERN EQUINE ENCEPHALITIS

Although designated as an “eastern” virus, EEE has a wide geographic distribution. It is found as far north as eastern Canada. Infection in the United States is primarily seen in the southeastern states, but it has been

detected in all states east of the Mississippi River and also in a number of western states. In recent years, intense focal activity has been reported in Wisconsin, Ohio, Massachusetts, and New Hampshire.

In the United States, most reported cases of EEE in horses occur in the northern parts of Florida and the Carolinas. Several hundred equine cases are confirmed each year, despite the widespread availability of vaccines.[300,301] In Florida, most horses that succumb to EEE are not vaccinated or have only received a primary vaccination series, although 17% to 30% of EEE-positive horses have had at least one primary series.[301] These horses are less than 3 years of age and are stock-type horses. There is no gender predilection.

In North America, EEE virus is perpetuated in a sylvatic cycle between avian hosts (passerine birds) and mosquitoes, primarily the ornithophilic mosquito, *Culiseta melanura*.[302] It is likely other mosquitoes, such as *Culex erraticus,* are important in nonavian forms of transmission, as demonstrate by recent studies in Alabama.[303] Indigenous passerine birds do not develop disease but develop sufficient titer viremia to allow transmission to feeding mosquitoes, with recent evidence showing cardinals to be efficient and important local reservoir hosts in the Southeast.[304,305] Secondary-vector or epidemic-vector mosquitoes feed on both birds and mammals and are likely biologic vectors precipitating mammalian disease. These mosquitoes probably transmit EEE to horses, humans, and other vertebrate species, yet these particular clinically affected mammalian hosts do not develop levels of viremia sufficiently high to allow further transmission of the virus by mosquitoes and are considered “dead-end” hosts.

985

986

Culiseta melanura, a temperate breeding species of mosquito, does not readily breed in southern Florida and the Caribbean, and EEE is not an endemic disease in this relatively focal region.[306] As such, sporadic reports or small epidemics of EEE disease are reported in horses in these areas, likely through migratory influx of viremic birds providing occasional sources of virus for secondary vectors. Apparently, these secondary vectors can initiate short-term outbreaks but cannot maintain the disease endemically.

35.2.11.2.2

WESTERN EQUINE ENCEPHALITIS

Historically, large outbreaks of WEE have been described in horses. The virus was first identified in association with a large epizootic in the San Joaquin Valley of California in 1930. Approximately 6000 horses were affected, with a case-fatality rate of 50%.[307] Over the last decade, there have been limited, sporadic reports of WEE in horses, likely reflecting vaccination and protective immunity gained by subclinical exposure.[308,309]

Culex tarsalis is the primary vector that maintains WEE virus in an enzootic cycle with birds, especially nestling passerines.[276,310] *C. tarsalis* population abundance is favored by a rapid increase in temperature after a cool, wet spring, resulting in the rapid melting of snow and flooding of rivers.[311] This species of mosquito also has a predilection for irrigated lands as breeding sites.[312] Other ornithophilic mosquitoes become infected as the summer progresses, and the infection eventually spills over to other types of birds, mammals, and possibly reptiles and amphibians. Most, if not all, of these infections are inapparent.

At least two variants of WEE virus (Fort Morgan and Buggy Creek) have been isolated in western North America and are transmitted between birds by swallow nest bugs *(Oeciacus vicarius)*.[313] The third variant, HJV, found east of the Mississippi River, has been isolated from horses dying of encephalitis, but information is limited on actual annual occurrence of disease.[282,283,313,314]

35.2.11.2.3

VENEZUELAN EQUINE ENCEPHALITIS

VEE virus is one of the most important human and veterinary pathogens in the New World.[290] The virus has been responsible for large outbreaks of disease in both humans and horses over large geographic areas. The first recognized outbreak of VEE occurred initially in equids in Colombia and then in Venezuela in 1935 and 1936, although it is speculated to have been active in this area since 1920.[315] Documentation of human disease occurred in a Columbian outbreak in the 1960s, when an estimated 50,000 to 100,000 equids (horses, mules, and donkeys) died and 250,000 humans were affected (mainly an influenza-like disease, but some cases of encephalitis and death). It is uncertain whether a 1969–1971 epidemic, first reported in Ecuador with subsequent spread to Central America, Mexico, and Texas, was related to the outbreak in Colombia or was caused by the use of an incorrectly inactivated subtype IAB strain vaccine.[316,317] VEE has the potential to spread rapidly within an equine population, with a case-fatality rate approaching 90% in some areas. After a long period without any evidence of clinical disease in horses, geographically extensive outbreaks have occurred in Chiapas (1993), southern Mexico, Venezuela and Colombia (1995), and in Oaxaca, Mexico (1996).[290,318–320] These outbreaks resulted in the demise of large numbers of horses, mules, and donkeys, and an estimated 75,000 to 100,000 human cases of disease occurred. Although the cause of these severe cyclic disease occurrences is still a matter of intense research, it can be assumed that severe epizootic VEE may continue to occur, with interepizootic periods of one to two decades.

Key to understanding the epidemiology of VEE is recognition of the differences in the basic biology of two transmission cycles, enzootic and epizootic, of this virus.[290] Certain strains of virus are found only in the enzootic cycle, usually subtypes I-E, II, III, and IV. These tend to be of low pathogenicity for equids and do not result in high levels of viremia in horses. The enzootic cycle centers around sylvatic rodents such as spiny and cotton rats, which have high natural infection rates and can develop viremia high enough to transmit VEE to mosquitoes.[321,322] Even opossums, bats, and shorebirds likely are important in dispersal of enzootic virus.[323] The subgenus *Culex* mosquito, *Melanoconion (Culex) cedecei,* is likely to be the most important vector of enzootic VEE.[324] This vector resides in tropical forests and swamps and feeds on small forest mammals at night, with activity peaking with high ambient temperature and rainfall.

Epizootic VEE viruses, primarily of the subtypes IAB and IC, occur intermittently.[325,326] These viruses are associated with variable but often high equine mortality (20% to 85%).[327] Efficient amplification with transmissible viremia by equids is the hallmark of epizootic VEE. Humans typically develop a flulike illness, with 4% to 14% exhibiting neurologic signs and symptoms.[323] Case-fatality rate for humans is approximately 1%. Several other species of mammals, including domestic rabbits, small ruminants, and dogs, develop potentially fatal clinical disease after VEE virus infection.[327] More than 100 species of birds have been either virologically or serologically associated with transmission of epidemic VEE virus. Birds may develop viremia as high as $10^{8.0}$ $TCID_{50}$/mL of blood.

The importance of equine infection in maintenance of epizootic VEE is evidenced by the observation that human disease has never been demonstrated in the absence of equine disease.[328] All mammalian hosts are capable of developing a high-titer viremia of approximately 10^5 to 10^7 plaque-forming units (PFU)/mL for up to 5 days, but the horse is likely to be the most important mammalian host in terms of vector capacity.

[290] In contrast with EEE and WEE, where horses are not considered to be a major source of virus for the vector, in VEE epidemics, horses are the most important amplifiers of virus activity.

Several species of mosquitoes from at least 11 genera have been determined to be naturally infected with epidemic strains of VEE virus.[329] Virus has also been isolated from *Culicoides* species (Ceratopogonidae) and blackflies (Simuliidae), but it is not known whether insects in these families are capable of biologic transmission of VEE virus.[299] During an epidemic, dogs regularly become infected and may be capable of virus amplification.[330] In addition, ticks, including the species *Ambylomma cajennense* and *Hyalomma trancatum,* may be capable of viral transmission.[290]

Several theories exist regarding the source of IAB and IC strains and how they persist in the environment between outbreaks.[290] Isolates that are virulent for horses do not appear to be transmitted in the interepizootic period.[331] Mutation of enzootic strains may allow the emergence of highly pathogenic virus and initiation of epizootics with this change in vector emphasis and equine morbidity.[332] This has been identified as the source of four epizootics. Some of these epizootics may have occurred secondary to the use of a modified live vaccine derived from the IAB strain.[317]

35.2.11.3 Pathogenesis

The virus genome is 9.7 to 11.8 kilobases in length and encodes both nonstructural and structural proteins.[333] 986
Alphaviruses replicate to high titer in the cytoplasm of infected cells and exit the cell by the budding of 987
preassembled nucleocapsids through the plasmalemma.[334] They cause cytopathic effects in a wide range of vertebrate cells in vitro. Virulence of VEE virus depends on systemic virus load rather than specific neurovirulence.[335,336] Both EEE and VEE have efficient intracellular replication and are pathogenic when inoculated intracerebrally.[337] Studies in mice demonstrate that neural invasion is likely to occur secondary to vascular infection or invasion through the olfactory epithelium.[338] In young mice, there is intense replication in osteoclasts of developing bone, possibly explaining why young animals and humans are much more susceptible to severe disease.

The regional lymph node is presumed to be the site of primary viral replication after the bite of a mosquito infected with EEE, WEE, or VEE virus.[264] The reticuloendothelial system is a major target in epidemic VEE infections. The viruses cause encephalitis after hematogenous or neuronal spread. Immunity, after both inapparent infection and clinical disease, as caused by EEE, WEE, and VEE, is long lasting in all species. Horses infected with EEE and WEE do not excrete infectious virus, and recovered animals are not persistently infected with virus.

35.2.11.4 Clinical Findings

Different strains of EEE, WEE, and VEE viruses may differ in their virulence not only for horses, but also for humans, certain domestic and wild animals, birds, and laboratory animals.[328] Clinical observations during epidemics of VEE indicate that the disease is generally less severe in donkeys (burros) and mules.[339] None of these viruses appears to cause clinical disease in their reservoir hosts indigenous to North and South America. Many human and equine infections, apart from those caused by highly virulent strains, are

subclinical. When disease does occur, broad differences exist in the clinical manifestations produced by the three virus complexes in horses and humans.

Eastern equine encephalitis and epidemic VEE viruses are generally more neuroinvasive than WEE and endemic VEE viruses. Children and young animals of all susceptible species are more likely than adults to develop clinical signs referable to infection of the central nervous system.[264,301,323,340,341] The incubation periods of EEE, WEE, and VEE vary from 2 to 3 days to, rarely, as long as 3 weeks. Inapparent infections in horses may or may not be accompanied by fever. In clinical cases, pyrexia is the first clinical manifestation of infection. Temperature has usually abated or is only moderately elevated by the time signs of encephalitis become evident. Neurologic signs are variable, but obtunded mentation, ataxia, paralysis, anorexia, and ultimately stupor occur in clinical cases. Irregular gait, grinding of teeth, incoordination, circling, staggering, head pressing, and hyperexcitability are also observed; clinical signs are progressive in nature. Severely ataxic animals may stand by leaning against walls or other objects and sometimes stand with their hindlegs crossed. Partial or even total blindness may be evident. In severely depressed horses the head hangs low with drooping ears, and the eyelids may be slightly swollen and partly closed, while the lips are flaccid and the tongue may protrude from the mouth. The profound depression associated with these virus infections give rise to the common name of “sleeping sickness.” Esophageal paralysis, as manifested by repeated unsuccessful attempts to drink, has also been described.

The course of disease in severely affected horses varies between 2 and 14 days. Almost all horses with EEE encephalitis die, regardless of the quality and intensity of clinical care. Horses with disease caused by VEE or WEE are more likely to survive than those with EEE-induced disease. At terminal stages, horses become recumbent, become comatose, and frequently exhibit seizure activity.

35.2.11.5

Diagnosis

Clinical signs and antemortem clinicopathologic findings are not specific for alphavirus infection. Viral and other encephalitides can cause abnormal cerebrospinal fluid (CSF), which usually consists, in the horse, of a moderate mononuclear pleocytosis with an increased CSF protein. Eastern equine encephalitis is unique in that acute infection frequently results in a neutrophilic pleocytosis. Because there is a high mortality rate associated with this disease, identification of a neutrophilic pleocytosis indicates probable EEE infection and offers the veterinarian a chance to prognosticate regarding the horse's survival.

It is paramount to obtain a definitive diagnosis for clinical signs of encephalitis in the horse, to justify and institute effective control measures, because of the risk of these viruses to the health and well-being of both humans and equine livestock. The viruses of EEE, WEE, and VEE frequently, but not always, can be isolated or detected after death in brain material of diseased horses by the use of cell cultures (e.g., Vero cells), intracerebral inoculation of suckling mice, and by detection of specific nucleotide sequences using reverse-transcriptase polymerase chain reaction (RT-PCR) technology.[342,343] Blood is an inappropriate specimen for virus recovery because no circulating organism is usually present when neurologic signs become apparent. In an epidemic situation, however, it may be possible to isolate the virus from nonencephalitic horses in the affected group, particularly if they have increased body temperature. The cytopathic or lethal effects of the virus in cell cultures or experimental animals can be inhibited by the use of specific antisera, and in this way the virus involved may be specifically identified.

Currently, there are no reliable antemortem diagnostic tests to detect virus in clinically affected horses, and serology provides the mainstay of presumptive antemortem diagnosis. The demonstration of specific IgM antibody (dilution of 1:400) suggests recent infection.[344] The detection of IgM antibody in CSF (if available)

is even more conclusive. Rising antibody titers to EEE, WEE, or VEE viruses in the sera of horses that survive can be detected by testing of acute-phase and convalescent-phase sera. Even in endemic areas, it is not possible to diagnose/differentiate EEE, WEE, or VEE in the horse with any certainty based on clinical signs and epidemiologic circumstances.

Rabies, hepatic encephalopathy, and equine protozoal myeloencephalitis are the major diseases that must be considered in the differential diagnosis in the Western Hemisphere. Other diseases that should be considered are equine herpesvirus 1 infection of the central nervous system, leukoencephalomalacia (a neuromycotoxicosis caused by the ingestion of maize infected with *Fusarium moniliforme*), and ataxia resulting from cervical vertebral malformation.

35.2.11.6

Pathologic Findings

In horses, brain lesions are thought to be the direct result of viral replication and are characterized by necrotizing encephalitis with neuronal dysfunction.[345] There are no consistent gross lesions in horses that die of EEE, WEE, or VEE. Histologically, neuronal necrosis with neurophagia, marked perivascular cuffing with both mono- and polymorphonuclear leukocytes, and focal and diffuse microglial proliferation are evident. The lesions are more pronounced in the gray matter than in the white matter of the brain. Lesions are most marked in the cerebral cortex, thalamus, and hypothalamus, whereas the spinal cord is mildly affected. More frequent and severe lesions are usually present in the cervical spinal cord than in lumbar cord segments.

987

988

35.2.11.7

Treatment

No known antiviral medications have demonstrated reliable activity against alphaviruses, and treatment of disease in affected horses is supportive. The survival rate for EEE infection is low compared with other infectious encephalitides. In most cases, horses die 3 to 5 days after onset of signs.

Corticosteroids should be considered as a component of therapy for horses with neurologic signs consistent with viral encephalitis and neutrophilic CSF. If administered early, corticosteroids (to reduce brain edema) and intravenous fluids may aid recovery. In human patients, treatment with methylprednisolone at 1000 mg/100 kg is often recommended. Administration of flunixin meglumine (1.1 mg/kg every 12 hours IV) or other antiinflammatory medications to horses with EEE does not often result in the dramatic response frequently observed in horses with West Nile virus. Mannitol (0.25 to 2.0 g/kg every 24 hours IV) may assist in the control of brain edema. Detomidine hydrochloride (0.02 to 0.04 mg/kg IV or IM) is effective for prolonged tranquilization.

Intravenous immunoglobin therapy has been used in people for its proposed anticytokine effect. Interferon-alpha (IFN-α) is a relatively common therapy. The recommendation for IFN-α therapy is based on anecdotal reports in the human and veterinary literature. Limited information regarding efficacy in the horse is available.

35.2.11.8

Prevention

The alphaviruses are not stable in the environment and are easily inactivated by common disinfectants. Mosquito control and immunization of horses are both important in control of EEE and VEE epizootics. Vector control can be achieved through reducing the breeding activities of mosquitoes by implementing appropriate water management systems, although this can be difficult in extensive areas.[346,347] The

widespread dispersal (usually achieved by aerial spraying) of insecticides has been used successfully, although several critical factors need to be considered before embarking on such a step. Concern over indiscriminate spraying of insecticides can be mitigated in some circumstances if the biology of the mosquito vector is well known. For example, in northern Florida, where EEE is endemic, treating the pools of water in which *Culiseta melanura* breeds with a larvicide is often practical and economically feasible on those farms with valuable horses. Swamps with soil types that support the breeding of *C. melanura* can often be recognized by the nonentomologist by the presence of the loblolly bay tree *(Gordonia lasianthus);* this broadleaf evergreen tree grows to a height of about 30 feet (9 m) and can easily be recognized by its white magnolia-like flowers and serrated leaf.[264,300,301] Risk assessment can be assisted by geographic mapping of large areas where mosquitoes breed by using thematic mappers, such as those on orbiting satellites.

Immunization of horses has proved highly effective as an adjunct to other control measures, particularly in outbreaks of VEE in which horses may serve as a source of infection for mosquitoes.[348,349] Currently, bivalent vaccines (usually consisting of formaldehyde-inactivated virus) are commercially available against EEE and WEE. These vaccines require a primary and a secondary immunization schedule about a month apart, followed by biannual boosters. The vaccines are not particularly effective in protecting foals and yearling horses, for unknown reasons.[350]

The 1969–1971 VEE epidemic in Central America and the southern United States was controlled partially by immunizing large numbers of horses with an attenuated VEE virus strain, TC-83.[348,349] This vaccine strain was produced by serial passage of an epidemic variant in guinea pig cell cultures. Because of concerns over the presence of low-level viremia in some horses and the possible transmission of vaccine virus between horses by mosquitoes and reversion to virulence, inactivated vaccines against VEE are now available for use in horses. These vaccines are not widely used in North America because they compromise the international movement of horses for competition and breeding.

Outbreaks of VEE might be completely prevented if sustained and widespread vaccination with live attenuated VEE vaccines was performed in Central and South America.[290] Public health and animal industry officials should consider maintaining vast quantities of the live attenuated TC-83 vaccine. The use of the formalin-inactivated vaccine (usually marketed as a multivalent antigen) is discouraged in VEE endemic areas because of the need for multiple vaccinations (and thus delayed onset of protection), short-lived immunity to VEE, lack of long-term compliance from agricultural officials and the horse-owning public in endemic locales, and concern of limited response to the live vaccine in horses immunized recently with a killed product.

Surveillance for encroachment of alphaviruses in new geographic locales is also paramount to control. Most southern U.S. states have encephalitis testing programs that offer subsidized testing for horses with suspected viral encephalitis. Enhanced passive surveillance for alphaviruses should be undertaken when environmental conditions are favorable. For example, hurricanes were implicated in the VEE outbreak in Mexico in 1995. Given that the United States has experienced intense hurricane activity in 2004 and 2005, enhanced surveillance for epizootic VEE should logically be undertaken.

Alphaviruses are pathogenic for people but require a vector for infection. The horse does not develop a sufficient level of viremia with EEE and WEE to act as a reservoir or amplifying host for these viruses. In contrast, horses are considered the most important species for amplification of virus in epizootic VEE. Therefore, control measures should be implemented to limit new exposure of horses in locales that are undergoing epizootic VEE. This includes restriction of horse movement; clinically normal horses may be viremic, and the disease can be translocated. Horses should be vaccinated and sprayed frequently with

permethrin-based products. Mosquito abatement efforts should be pursued. Blood and tissues from VEE horses should be handled as infectious and biohazardous materials, with tissues from EEE and WEE horses handled as such.

35.2.12 MISCELLANEOUS AND FOREIGN EMERGING VIRUSES CAUSING NEUROLOGIC SIGNS

Since the encroachment of West Nile virus (WNV) in 1999 into North America, the potential for emerging foreign disease with widespread impact has been realized. Given the opportunity, many other viral infections could become established in new countries as a result of the globalization of the horse industry. Because of its close genetic relationship to WNV, Japanese encephalitis is one of the most likely candidates. The reader is directed to the WNV section; these diseases are highly similar, and prognostication would be the same. What is unknown at this time is the effect that widespread WNV vaccination will have on the severity of a North American outbreak. The list in Table 35-4 is not exhaustive and includes only the more frequently reported causes of viral encephalitis.

988

989

Table 35-4 Miscellaneous Emerging Viruses that Cause Neurologic Disease

Name	Classification	Transmission	Country of Origin
Getah/Ross River	Alphavirus	Mosquito	Japan, Hong Kong, Se Sia, Korea, India, Australia, and South Pacific
Borna	Bornaviradae	Direct contact	Germany, Northern Europe
California serogroup	Bunyaviridae	Mosquito	Africa, Europe, Asia, North America, South America
Equine encephalosis	Orbivirus	*Culicoides*	Africa: South, Kenya, Botswana
Hendra/Nipah	—	Direct contact	Africa: South, Kenya, Botswana

35.2.12.1 Getah/Ross River Viruses

The Semliki Forest complex of the Togaviridae are widespread throughout their geographic range, either in the Orient (Getah) or South Pacific (Ross River).[351,352] Although closely related, there is little overlap of these viruses. As with the North American alphaviruses, these viruses are transmitted by mosquitoes (*Aedes*, *Anopheles*, and *Culex* species).[353–360] With Getah virus (GV) the reservoir is not known, although swine appear important in its transmission to mosquitoes.[360–363] Other feral species are not firmly established. With Ross River virus (RRV), marsupials are important reservoirs.[364] With GV, horses might develop sufficiently high viremia to transmit virus, but this is unlikely with RRV.[365–367] Many animals have been found to be seropositive to GV, including ruminants, and seroprevalence in horses varies from less than 10% to over 90%.[360,368–370] RRV is endemic in horses and widespread, with seroprevalence ranging from 50% to 80% in Australian horses.[351,371–373]

Getah virus is likely more pathogenic in horses than RRV.[365,368,369] Clinical signs include pyrexia, edema of the limbs, and stiff gait. Horses may also develop urticaria and submandibular lymphadenopathy. The course of GV disease is 7 to 10 days. With RRV, horses also develop fever, lameness, swollen joints, inappetence, generalized stiffness, and even colic.[351,371,373] High rates of mortality are not a feature of either virus.

Serologic detection of antibody is the mainstay of diagnosis of these viruses, although a vaccine against GV complicates diagnosis.[374–376] RRV can be isolated from the blood of horses during the disease course. Pathologic changes associated with these viruses are seldom described because of their low mortality. Horses primarily develop perivascular inflammation in the brain.

Treatment is supportive; no antiviral is specific for alphaviruses. A vaccine for GV is available in Japan.

35.2.12.2

Borna Disease

Borna disease is a cause of encephalitis first reported in horses in Borna, Germany, in the nineteenth century, with identification in other Northern European countries, such as Switzerland, Liechtenstein, and Austria.[377] Unconfirmed outbreaks have been reported in the Middle East and Japan.[378] The Borna disease virus (BDV) is linked to other regions through serologic testing and identification of antibodies in horses from Turkey, Israel, Iran, and the United States.[379–382] Other species noted with clinical signs of BDV include small ruminants, cattle, rabbits, cats, and dogs.[383]

The etiologic agent of Borna disease is a nonsegmented, negative-sense, single-stranded RNA virus of the order Mononegavirales, family Bornaviridae.[384–386] The viruses of Borna disease and Near Eastern encephalitis are indistinguishable. Importantly, with complete sequencing of the genome, several distinct virus clusters occur geographically.[381,387,388] In Germany, Borna has endemic foci centrally and south.[377,381,385] Subclinical exposure in horses is between 10% and 20%, with seroprevalence as high as 50% in stables with disease.

The Borna disease virus is shed through nasal and lacrimal secretions and in the urine of infected animals, so direct contact is suspected.[383,385,389] BDV is resistant to drying and other adverse environmental conditions. Outbreaks in horses in the Middle East may represent transmission from a dense population of infected wild birds, and recurrent outbreaks in Germany have been thought to originate from birds that have migrated from the Near Eastern countries.[377,381,385] Most outbreaks in horses occur in the early spring or autumn.

It is assumed that BDV enters the horse though intranasal infection and migrates to the brain transaxonally.[383,390,391] Direct replication occurs in neurons and glial cells, with spread to peripheral nerves and retina. Infection with BDV is persistent, and Borna disease has a slow onset thought to be caused by chronic inflammatory reaction in the brain. The lesion resembles that of lymphocytic choriomeningitis virus (LCMV) infection, in which the virus induces a cell-mediated response that disrupts and replaces functional aspects of the neuropil.

The clinical signs of Borna disease in large animals are similar to those of the other equine encephalitides.[377] In moderate to severe cases, horse die 1 to 4 weeks after onset of disease. In mild cases, recovery can be spontaneous; however, a chronic disease can occur with recurrent exacerbations. Typical clinical signs include ataxia, head tilts, muscle fasciculations, hindlimb paresis, and localized cutaneous hyperesthesia or

hypoesthesia. Aggressive behavior may be noted. In ruminants the clinical signs include head tremors, hyperesthesia, ataxia, anorexia, propulsive walking, coma, and convulsions.

For antemortem diagnosis, antibodies to the agent may be found in the serum and CSF of most infected animals by ELISA, indirect fluorescent antibody (IFA), and Western blot.[377,382] Some work indicates that CSF antibodies are more likely to be found in clinically affected horses than normal horses. There is often a mononuclear pleocytosis with high protein concentration. Enhanced-sensitivity PCR techniques have demonstrated virus in the CSF and peripheral mononuclear cells.[392] The criteria for diagnosis include a horse with neurologic abnormalities testing antibody positive for BDV in serum or CSF, or a horse with neurologic signs and appropriate histopathologic changes.[377,383]

Pathologic abnormalities resemble those of a viral encephalomyelitis, and confirmatory diagnosis is by immunohistochemistry (IHC), virus isolation, and detection of viral nucleic acids.[389,392–395] The characteristic microscopic lesion of Borna disease is the Joest-Degen inclusion body in the neuronal nucleus, but this is not always observed. Virus is detectable easily with monoclonal or polyclonal antibodies. Histopathologic changes are those of a typical polioencephalomyelitis, with a particular loss of neurons in the hippocampus. There is involvement of the gray matter of the olfactory bulb, basal cortex, caudate nucleus, thalamus, hippocampus, and medulla oblongata.

989

990

No antiviral agents are available for BDV, and use of the amantadine sulfate (developed for treatment of influenza infection) is controversial.[396–398] Likewise, vaccination as a protective strategy is controversial. It is widely assumed that a modified live vaccine would offer more protection; however, the live vaccine available until the early 1990s in Germany was removed from the market because of questionable efficacy.[396]

Controversy also surrounds the zoonotic potential of BDV. Mental health patients, in particular schizophrenics, have been associated with infection through serologic testing.[399–401] However, normal unaffected humans have also been found to be antibody positive. Thus the causality of this virus and the neurologic dysfunction, mainly characterized by altered behavior and perception in people, remain to be firmly elucidated.

35.2.12.3 Hendra/Nipah Viruses

In 1994 an outbreak of a previously unreported illness occurred in horses and humans in Hendra, a suburb of Brisbane, Australia.[402,403] A single mare brought into a stable died 2 days after arrival. In the following 2 weeks, 17 horses at the same facility developed respiratory and neurologic signs; several died or were euthanized. Two people that had close contact with the original mare also developed a flulike illness; one survived, but the other died from multiorgan involvement and cardiac arrest. Originally classified as a morbillivirus, Hendra virus was found to be similar to Nipah virus, was isolated from tissues of affected horses and people, and was believed to be the etiologic agent, as proved by development of similar disease in healthy horses after challenge with tissue homogenates from affected animals.[402,404,405] Nipah virus primarily causes respiratory disease in pigs and respiratory and neurologic disease in humans.[404,406] Infection of horses with Nipah virus has been indicated by serologic testing only in a few horses and in the brain of one horse. These two viruses occupy a new genus, *Henipavirus,* family Paramyxoviridae, subfamility Paramyxovirinae, order Mononegavirales.

These viruses are primarily bat viruses (genus *Pteropus,* fruit bat), with approximately half the bats testing positive in an endemic focus, whereas other mammalian hosts are comparatively seronegative.[407,408] Transmission is thought to be by direct contact of horses, likely with secretions such as urine, aborted fetuses, and other reproductive fluids.[407–409]

The predominant clinical signs of equine hendravirus infection are those of respiratory disease: tachypnea, dyspnea, frothy nasal discharge, tachycardia, fever, anorexia, and death.[405,410] Signs of neurologic disease that may accompany the respiratory signs include dullness and ataxia.

Sera from infected horses are positive for antibodies to the virus.

After infection by direct contact, Hendra/Nipah virus appears to localize in the respiratory tract epithelium.[404,405,411,412] Experimentally, however, infections can occur by all routes, resulting in respiratory shedding of the virus. As with other paramyxoviruses, there is widespread dissemination of the virus in lung, liver, kidney, lymph nodes, and blood after infection. Infection primarily involves the vascular endothelial cells with pulmonary edema, although CNS pathology is similar to that caused by distemper or measles.

The infection results in an interstitial pneumonia with focal necrotizing alveolitis, subpleural edema, and syncytium formation in the vascular endothelium.[403,410]

Treatment is supportive and symptomatic care only. No specific agents have been shown to combat the Hendra/Nipah viruses.

35.2.12.4

California Serogroup Diseases

Bunyaviruses are mainly mosquito-transmitted viruses and are found worldwide. Some of these viruses are known to be transmitted by *Culicoides* flies as well.[361,413–427] Approximately 12 serotypes of these viruses, collectively known as the California serogroup, have been isolated in North America, South America, Africa, Europe, and Asia. The viruses have various names, depending on location or host and possibility for equine infection, including snowshoe hare, Jamestown Canyon, Cache Valley, and Main Drain. Transmission is mainly by *Aedes* mosquitoes.

Clinical signs are consistent with encephalitis and include ataxia, weakness, stiff neck, head pressing, and dysphagia. Systemic signs include tachycardia and fever. Horses that recover generally do so in 1 week.

35.2.12.5

Encephalosis

Th virus for encephalosis is closely related to bluetongue virus and African horse sickness (AHS) virus and is an *Orbivirus*.[428,429] *Culicoides* species transmit this virus to horses of South Africa, Kenya, and Botswana.[429–432] Because this virus is morphologically similar in cell culture to AHS virus, correct identification of this virus sometimes is not made. There is widespread subclinical exposure of this virus to horses throughout endemic regions, and several different serotypes exist.

Although subclinical disease is the most likely manifestation of encephalosis, the virus was originally named for isolation from a horse with typical signs of encephalitis.[433] In addition to signs of acute encephalitis,

horses will demonstrate systemic signs of fever, depression, and facial edema. Cardiac failure has been described, and pregnant horses may abort.

Correct testing that is group specific for encephalosis virus, but not for AHS or bluetongue virus, should be performed on serum from affected horses.[428,434–437] Final, definitive diagnosis is difficult even postmortem; cerebral edema, enteritis, cardiac myodegeneration, and fibrosis are seen.

There is no recognized treatment or prevention for encephalosis.

35.2.13 WEST NILE VIRUS

West Nile virus (WNV), one of more than 70 single-stranded RNA viruses in the *Flavivirus* genus of the family Flaviviridae, causes encephalitis in humans and other mammals and encephalomyelitis in equids.[438] Flaviviridae viruses contain many important veterinary and human pathogens, with at least half of these members classified as "zoonotics."[439] Historically and currently, investigations of these viruses have resulted in some of the most important scientific landmarks in human and veterinary health.

The Flaviviridae are composed of positive-sense, single-stranded RNA, measuring approximately 50 nm with a spherical, enveloped virion.[439–441] Most of the virus is composed of three structural proteins consisting of the icosahedral capsid (C), premembrane (prM) and membrane (M), and envelope (E).[442–444] The E protein is the immunodominant protein and consists of the neutralizing epitopes. There are three domains, with domain II involving virus binding in the brain and III important for vector and host virulence.[445,446]

The nonstructural proteins, seven in number, are essentially involved in synthesis of RNA.[447,448] The glycoprotein NS1 is essential for virus function and appears important for cell activation as part of viral synthesis.[449–451] NS1 also is found on cell membranes of infected cells and must interact with the other NS proteins for function.[449–451] NS3 is highly conserved between flaviviruses; at the N-terminal, it encodes a serine protein with sequences consistent with the trypsin superfamily, and at the C-terminal, it encodes RNA helicases and triphosphatases.[452] The NS4b protein appears to block host antiviral cytokines.[453] The NS5 protein is essential for viral replication by forming the "cap" at the 5′ end of a genome.[443,453,454]

West Nile virus is thought to infect the cell through glycoprotein receptors that are likely highly conserved in respective hosts.[439–446] This is further supported by the ability of WNV to infect and replicate in many cells. After binding, the viral membrane fuses with endosomal vesicle membrane, and the nucleoprotein is released into the cytoplasm. Alternating periods of replication and translation of viral proteins occur, and immature virions, still with the prM, accumulate in vesicles and are transported through the host secretory pathway, where the E and prM proteins are modified. The virus-laden vesicles are transported to the plasma membrane and released by exocytosis. Mammalian cells release progeny virus within 10 to 12 hours after infection.

35.2.13.1 Epidemiology

The life cycle of WNV consists of transmission by hematophagous mosquitoes to an avian host; with amplification occurring in both these hosts.[455] For maintenance, the virus must be cycled between biologic vectors, and presumably, vertical transmission occurs within the vector for season-to-season maintenance.[456]

Passerine birds are likely the most important nonvector reservoir hosts. Horses and humans are dead-end hosts because they do not amplify the virus in quantities sufficient to infect mosquitoes.

Other modes of transmission include oral infection of both avian and mammalian hosts, most notably predator birds and felids. Birds can shed WNV both orally and cloacally.[457–461] Virus is high enough in the blood of humans to be borne through blood and organ contamination by subclinical WNV-positive donors and can be transmitted vertically through placenta and milk.[462–468]

Initial manifestations of WNV disease occurred in humans and were characterized as flulike or febrile illness.[438] Subsequent outbreaks of illness were focal and sporadic, with children more susceptible to actual disease.[455] In endemic areas, most humans and horses demonstrate increased risk of spontaneous seroconversion with age.[457,461,469,470] In the last decade, WNV outbreaks began increasing in both frequency and severity, with neurologic disease and higher mortality in birds, horses, and humans. Before 1999, WNV caused focal intense outbreaks in horses in the Middle East and Europe.[461,470–472] The first year the virus occurred in New York, several dozen cases of equine WNV occurred by 2001. The outbreak spread westward and reached epizootic proportions, infecting large numbers of immunologically naive horses.[473–475]

Equine disease in the United States caused by WNV peaked in 2002 with the report of 15,257 cases that year (U.S. Department of Agriculture [USDA], 2003). Birds have developed natural immunity to WNV, so relatively fewer human and equine cases have been reported, especially in the Northeast and Southeast. However, overt WNV clinical disease still occurs. There were 3000 human cases and 119 human fatalities from WNV reported to the Centers for Disease Control and Prevention (CDC) in 2005. The average number of equine cases has been about 1000/year. As of January 2006, the official CDC count of equine WNV was more than 23,000 U.S. cases (Jennifer Lehman, personal communication). Horses with clinical signs of WNV disease reportedly have a 28.4% to 38% mortality rate.[473,476,477]

By 2005, WNV had been identified in all the 48 continental U.S. states.[478] Canadian provinces reporting disease include Quebec, Ontario, Manitoba, Saskatchewan, and Alberta, with New Brunswick and Nova Scotia reporting evidence of WNV-positive birds.[479] In Latin America, serologic evidence of WNV has been detected in the Dominican Republic, Mexico, Guadeloupe, El Salvatore, Puerto Rico, Cayman Islands, Jamaica, Belize, and Cuba.[461,470,480–484] The incidence of equine and human disease appears low for Central America, South America, and the Caribbean compared with the United States.[485] A decrease in the virulence of the North American strain has been reported, however, and other flaviviruses occur in Central and North America. Cross-protective immunity may also account for the decreased incidence in these locales.

The *Culex* mosquito is considered the most important vector of WNV in North America, although the virus has been detected in more than 60 species of North American mosquito.[461,462,486–489] *Culex pipiens*—positive pools are most frequently detected in the northeastern United States, with *Cx. tarsalis* constituting the majority of positive pools in the West, and *Cx. quinquefasciatus* and *Cx. nigripalpus* in the Southeast.[486,490–503] In the Southwest, epidemics in 2004 were associated, in decreasing frequency, with *Cx. quinquefasciatus*, *Cx. tarsalis*, and *Cx. pipiens*.

Little is known regarding the actual vector of transmission to the horse itself. Blood meal analysis supports *Cx. pipiens* as primarily avian feeders, whereas mammalian feeders include mainly *Anopheles quadrimaculatus, Coquillettidia perturbans,* and *Aedes albopictus*. Recent analysis of *Cx. quinquefasciatus* has detected both human and bird feeding, and *Cx. salinarius* reportedly has widest range of host feeding.[504]

Culex mosquitoes require a blood meal of approximately 10^5 to 10^7 PFU/mL of virus for 30% to 100% of mosquitoes to obtain infection with WNV, respectively.[505] Experimental infection of horses by mosquito transmission studies is accomplished with *Aedes aegypti* and *A. albopictus*.[506,507]

In ticks, transtadial transmission has been inconsistently documented in *Ixodes* species.[508,509] Under experimental conditions, *Carios capensis* transmitted WNV to ducklings, and *Ornithodoros moubata* transmitted WNV to mice.[509,510]

More than 300 species of birds have been reported "WNV positive" in the United States, with 16 new species identified during the 2005 season.[511] Passeriformes and Charadriiformes obtain the highest titers with the longest persistence and viremia, and tissue levels can consistently exceed 10^8 PFU/mL.[460] The house sparrow is considered the most important amplifying host.[460] Although susceptible to fatal infections, corvids develop very high viremia and still are likely efficient reservoirs.[457,459,460,512] Corvid susceptibility to WNV is notable in the North American outbreak. Early studies with the Egyptian WNV strain, however, produced high mortality in crows.[513,514]

With its vector requirements, WNV in horses and humans is seasonal in temperate regions (with expected year-round activity in subtropical regions).[497,504,515,516] Late September and October are times of peak incidence of disease, with July representing the start of intense WNV activity. Temperature-dependent spatial modeling supports these disease dynamics, with risk increasing from 25% in late August to more than 75% by the second week of September.[517–519] A drop in ambient temperature usually results in a rapid decrease in reporting activity.[520,521]

Age is a factor in susceptibility to neuroinvasive disease, as reported for both people and horses.[461,472,522–525] Although men are more frequently affected with neuroinvasive disease, there appears to be no breed or gender predilection in the equine. In fact, in one study examining outcome parameters, female horses were 2.9 times more likely to die than male horses with neurologic signs.[522–524] This may reflect pasture-associated exposure with broodmares or longer lifespan due to reproductive value.

991

992

Multiple free-ranging and domesticated mammals, including the big brown bat, little brown bat, eastern chipmunk, eastern gray squirrel, eastern striped skunk, white-tailed deer, and brown bear, have demonstrated spontaneous seroconversion to WNV.[461,492,505–511,526] Neurologic disease has been diagnosed in WNV-positive gray squirrels and fox squirrels, and febrile disease has been described in cats.[527,528] Oral infection has been induced in experimental infection of cats. Both farmed and free-ranging alligators can obtain extremely high viremia and may be an important reservoir in the Southeast.[526] In farm-raised alligators, cloacal shedding has been demonstrated, with oral infection likely. Serologic evidence of infection has been demonstrated in domestic dogs. Llamas have been reported to develop neurologic disease.[529,530]

35.2.13.2 Pathogenesis

The syndrome of WNV in the horse consists of neurologic signs, with abnormalities in mentation, the spinal cord, and cranial nerves, primarily of the midbrain and hindbrain.[474,531–540] Virus localization in the motor neurons of the thalamus, medulla, and pons likely accounts for changes in behavior.[532,541,542] Change in consciousness occurs frequently, likely caused by lesions in the midbrain and rostral pons affecting the

reticular formation.[540,543] The reticular formation projects to the thalamus, which in turn sends diffuse projections and is the source of cholinergic stimulation to the entire cerebral cortex.[540] Thus, disturbances of the reticular formation and the midbrain may induce the behavioral changes observed, which range from aggression to somnolence.* Spinal deficits are characterized as multifocal, asymmetric, with weakness and ataxia likely reflecting direct infection of the spinal cord, interruption of motor tracts in the hindbrain, and loss of fine motor control through infection of the large nuclei of the thalamus and basal ganglia.[546,547] Loss of fine motor control is evidenced by involuntary skin and muscle fasciculations, tremors, and hyperesthesia, and a predilection for the basal ganglia likely results in Parkinson-like syndrome. Infection in the pons and medulla oblongata can explain clinical deficits of cranial nerves (CNs) VII, XII, and IX.[548]

It is unknown how WNV invades the central nervous system (CNS); WNV is proposed to cause minimal viremia, with replication in the lymph nodes, followed by invasion into the CNS across the blood-brain barrier.[446] Alternatively, there may be transaxonal transmission.[438,519] In rodent models the virus is capable of invading the CNS after peritoneal challenge, demonstrating a primary predilection for neural tissues.[549,550] Viremia occurs 3 to 5 days after experimental challenge and lasts 24 to 72 hours, with dissemination into the CNS at 4 to 6 days after inoculation. Intrathecal infection of horses results in clinical signs 7 to 10 days after inoculation. WNV directly infects nerve cell bodies, and in rodents, initial replication occurs in the basal ganglia, with dissemination later to cortex, cerebellum, and hippocampus. The large neurons of the ventral or anterior horns are infected late in infection, and in mammalian hosts, neuronal viral load is low. As noted earlier, cell lysis occurs with viral replication, but WNV also induces apoptosis in neurons, which likely accounts for most of the pathophysiology.[549,551]

* References 532, 534, 538, 541, 542, 544, 545.

35.2.13.3

Clinical Findings

When infected with lineage type I WNV, horses develop neurologic disease, whereas infection with lineage type II viruses is subclinical in nature.† Both systemic and neurologic abnormalities are observed in horses. Systemic clinical signs occur initially and include a mild to moderate increase in rectal temperature (38.6° C to 40°C; 101.5° F to 104.0°F), anorexia, and depression. Presenting complaints can be insidious and can manifest as abdominal pain or lameness, including a bizarre gait, as in rabies infection in the horse. The occurrence of neurologic symptoms is frequently sudden and progressive, and the exact course of disease in any one animal is unpredictable. The most unique manifestations of equine WNV encephalomyelitis are changes in personality and development of fasciculations. Periods of hyperexcitability and apprehension are common and can be severe, to the point of aggression. Change in personality is manifest by a quiet horse becoming hyperexcitable and an abnormally aggressive horse becoming submissive. Some horses develop attention deficits, even with bouts of sleeplike behavior during activity, resembling cataplexy or narcolepsy. Fasciculations, although not pathognomonic, are so notable that many clinicians base their preliminary diagnosis on their occurrence. These tremors usually involve the face and neck muscles but can involve all four limbs and the trunk so that normal activities such as walking, eating, and interaction with handlers and other horses are interrupted. Rapid blinking of eyelids is common (and stimulated with a penlight), and horses likely are photophobic.

One of the initial signs of motor abnormality is bradykinesia, characterized as a short, slow-stilted gait described by observers as “lameness,” with laminitis being a common differential at this stage. Spinal abnormalities are characterized by ataxia and paresis that can be highly asymmetric or can involve only one or both forelimbs or hindlimbs. Cranial nerves are frequently abnormal, with weakness of the tongue, muzzle

deviation, and head tilt most common. The tongue abnormalities can also be associated with dysphagia and choking. Abnormalities of the cauda equina also occur and consist of stranguria and rectal impaction. All these clinical signs are variable, and after initial signs abate, about one third of clinically affected horses experience an increase in severity of clinical signs within the first 7 to 10 days of onset. Overall, about 30% of the horses progress to complete paralysis of one or more limbs. Most of these horses are euthanized for humane reasons or die spontaneously.

In many horses, clinical signs generally improve within 3 to 7 days of displaying onset. After 3 to 5 days, horses that are recovering or stabled may exhibit a sudden recurrence of signs. Clinical signs may be of short duration, or horses may become suddenly recumbent and either die or recover only with prolonged treatment. Horses that become recumbent often need aggressive supportive care. Once the horse has demonstrated significant improvement, full recovery within 1 to 6 months can be expected in 90% of patients.[554] Residual weakness and ataxia appear to be the main problems; however, personality changes were reported as well.[554] In humans, some patients have experienced long-term inflammation of the meninges, and others have experienced the long-term loss of the use of one or more limbs. In addition, mild to moderate, persistent fatigue on exercise and chronic headache have also been noted.

35.2.13.4

Diagnosis

In general, complete blood count (CBC) and serum biochemistry profiles of WNV horses are normal.[531] Horses may present with a mild absolute lymphopenia, elevated muscle enzymes, and hyponatremia, which has also been described in humans with viral encephalitis. Cerebrospinal fluid cell counts are normal to elevated and mononuclear in nature, with protein levels also normal to elevated.[555]

992

993

Confirmation of WNV infection with encephalitis in horses begins with assessment of whether a horse meets the case definition based on clinical signs occurring in an area in which WNV has been confirmed in the current calendar year in mosquito, bird, human, or horse.[473] Serologic testing relies on the development of immunoglobulin M (IgM) and neutralizing-antibody responses in acute-phase serum, as tested by an IgM-capture enzyme-linked immunosorbent assay (MAC-ELISA) and neutralization testing (NT), respectively. In serologic confirmation of flaviviruses and most arboviruses, the neutralization format is considered the “gold standard” because of the specificity of neutralizing antibody generated in response to these viruses. Until fall 2001, a positive IgM titer of 1:400 or higher and a plaque reduction neutralizing-antibody test (PRNT) titer of 1:10 or higher on a single serum was considered confirmatory for serodiagnosis of WNV encephalomyelitis in a horse exhibiting appropriate clinical signs. Since 2001, reliance on the PRNT for serologic confirmatory diagnosis in horses has diminished because of the availability of WNV vaccination for horses. Vaccination induces formation of neutralizing antibody and likely confounds interpretation of the PRNT. Most diagnostic laboratories use MAC-ELISA for confirmation of WNV disease (because consistently detected IgM rarely occurs after vaccination) in the horse, and the sensitivity and specificity of this test are approximately 81% and 100%, respectively.[556]

Other means of confirmation include postmortem detection of WNV by PCR, culture, and IHC in CNS tissues. Several methods of WNV nucleic acid testing in equine tissue have been described, including nested PCR targeting the E protein, which demonstrated sensitivity for relatively low viral load, and real-time PCR. The E-protein target appears less sensitive; however, the NS5 target has detected WNV nucleic acids in CNS tissues, heart, and intestine of clinically affected horses.

35.2.13.5

Differential Diagnoses

Even if WNV is suspected based on time of year and vaccination history, other infectious CNS diseases should be considered in the differential diagnoses, including alphaviruses, rabies virus, equine protozoal myeloencephalitis (EPM), equine herpesvirus type 1 (EHV-1), botulism (less likely), and verminous meningoencephalomyelitis *(Halicephalobus gingivalis*, *Setaria*, *Strongylus vulgaris)*. Alphaviruses, rabies, *H. gingivalis* infection, hepatoencephalopathy, and leukoencephalomalacia are rapidly progressive cortical signs characterized by behavioral alterations, depression, seizure, and coma. The appearance of seizure and coma is rare in WNV horses but can occur. Cranial nerve signs in EEE and WEE are also common, including head tilt, pharyngeal/laryngeal dysfunction, and paresis of the tongue. The incidence of WEE in horses is fairly low in the United States, but mortality and severity of clinical signs would more closely resemble WNV. Differentiation from rabies is problematic because clinical signs in horses with rabies frequently include ataxia, weakness, or gait abnormalities. Although there are periods of somnolence, blindness, and some cranial nerve deficits, WNV horses appear to become rapidly recumbent or stabilize over several days, as opposed to rapid deterioration with EEE, rabies, and *H. gingivalis*. Spinal disease caused by EPM is a more difficult differential if horses with WNV are not febrile and do not exhibit excessive muscle fasciculations. Noninfectious causes to consider include hypocalcemia, tremorigenic toxicities, hepatoencephalopathy, and leukoencephalomalacia.

Serum titers should be evaluated for recent exposure to other encephalitides, including EEE, WEE, and EHV-1. An IgM-capture format is appropriate for EEE and WEE, but for the NT format, paired titers are necessary in vaccinated horses. Because WNV can present with asymmetric weakness and ataxia, Western blot testing for EPM should also be performed on CSF.

35.2.13.6

Pathologic Findings

Flaviviruses cause polioencephalomyelitis (inflammation of gray matter), with lesions that increase in number from the diencephalon through the hindbrain and frequently increase in severity caudad in the spinal cord.* Gross pathologic findings are limited in WNV infection in the horse. The meninges may be congested. Small to moderate-sized foci of hemorrhagic discoloration can be observed in the brain and spinal cord. The most common areas observed in the brain include the basal ganglia, rostral colliculus, and both pons and medulla. The most common sign of spinal changes appears in the lumbar cord. Edema and softening of tissues are also common.

Histopathologic changes are consistent with viral infection and neural cell death. The basal ganglia, thalamus, pons, and medulla have the highest numbers of lesions, characterized by two to several cell layers of mononuclear perivascular cuffing. Predominantly confined to the gray matter, there are also collections of mononuclear cells within the parenchyma (gliosis). By contrast, this is limited in the cortex and cerebellum. Neuronal damage includes chromatolytic neurons and neuronophagia. In long-standing disease, areas of neuronal dropout may be seen. In the spinal cord, there is perivascular cuffing, gliosis, and damaged neurons. The inflammation associated with the neuropil is confined mainly to the gray matter.

35.2.13.7

Treatment

To date, no antiflavivirus compounds are marketed. Therapy is supportive for these infections, although several experimental inhibitors of RNA virus replication are under development.[558–563] Accurate assessment of the direct effect of any pharmacologic intervention in WNV disease is difficult because horses can begin the recovery process within 72 hours of onset of clinical signs. Flunixin meglumine (1.1 mg/kg every 12 hours IV) early in the course of the disease appears to decrease the severity of muscle tremors and fasciculations within a few hours of administration. To date, much of the mortality in WNV horses results from euthanasia of recumbent horses for humane reasons rather than spontaneous fatality. Recumbent horses are mentally alert and frequently thrash, sustaining many self-inflicted wounds and posing risk to personnel. Therapy of recumbent horses is generally more aggressive and may include dexamethasone sodium (0.05 to 0.1 g/kg every 24 hours IV) and mannitol (0.25 to 2.0 g/kg every 24 hours IV). Detomidine hydrochloride (0.02 to 0.04 mg/kg IV or IM) is effective for prolonged tranquilization. Low doses of acepromazine (0.02 mg/kg IV or 0.05 mg/kg IM) provide excellent relief from anxiety in both recumbent and standing horses. Until EPM is ruled out, prophylactic institution of antiprotozoal medications is recommended. Other supportive measures may include oral and intravenous fluids and antibiotics for treatment of infections that frequently occur in recumbent horses (wounds, cellulitis, and pneumonia).

Interferon-alpha is a relatively common therapy,[560,564,565] based on differences in genetic loci to immune response elements that induce nonspecific immunity in mice. The success of IFN-α rests on anecdotal reports in the human and veterinary literature. Intravenous WNV-specific immunoglobulin therapy has also been described, and in a blind controlled placebo trial with low numbers of animals, the risk for development of recumbency was lower. Otherwise, outcomes and severity were the same. In human therapy, high-dose glutamate has been pursued to prevent neuronal cell death.[566] Another experimental investigation in mice involves β-lactam inhibitors that stimulate GLT1, a chemical that activates glutamate.[567,568]

993 994

35.2.13.8

Prevention

Initial epidemiologic studies indicated a point source for WNV infection, demonstrating that the outbreak could be controlled by vaccination.[474,476,477,544] Presently, three vaccines are licensed for prevention of WNV viremia in the United States. Vaccination before the mosquito season is optimal. Two of these vaccines, a killed product and a recombinant product based on the canarypox vector, require an initial injection followed in 3 to 6 weeks with a booster injection.[569] Most manufacturers recommend more frequent vaccination in areas with year-round mosquito seasons. However, the recently licensed third vaccine demonstrated 12 months of immunity against severe intrathecal challenge with WNV. Limited information is available regarding long-term immunity with the other vaccines, given that the duration of immunity was tested using the mosquito model of WNV infection, which results in seroconversion and viremia as a measure of efficacy. Horses that have recovered from clinical WNV have long-term immunity against WNV and should not require immunization.

West Nile virus is a zoonotic in that a bird reservoir maintains the virus in an endemic life cycle in the environment, with transmission by mosquito to humans. There is little risk of disease by direct contact with a horse. However, the ecology of horse pastures and stables with standing water, a high degree of biologic debris, and “bridge” vectors that feed on mammalian populations pose a risk to people. The same type of management tactics for prevention are important for humans, except that there is no vaccine and deet-based

products are recommended for protection. The North American epidemic of WNV has demonstrated new modes of transmission involving blood-borne and occupational risks. Blood-borne transmission can occur between a viremic host and accidental needle injection. In addition, occupational infection has occurred through necropsy of avian hosts. Veterinarians and horse owners should institute personal protection with appropriate clothing, gloves, and eye protection when coming in contact with animal tissues during the arbovirus season.

35.2.14 OVINE ENCEPHALOMYELITIS (LOUPING ILL)

35.2.14.1 Definition and Etiology

Louping ill is an acute, fatal encephalomyelitis of sheep that occasionally infects humans, wild ruminants, horses, and cattle.[570–572] The disease has been reported in England, Scotland, Ireland, Norway, Turkey, and Bulgaria.[573–575] The etiologic agent of louping ill is a neurotropic, single-stranded RNA virus (flavivirus) that is transmitted by primarily the tick *Ixodes ricinus*, as well as by *Rhipicephalus appendiculatus, Ixodes persulcatus,* and *Hemaphysalis anatolicum*. Most outbreaks occur in swampy areas with dense populations of infected ticks and wild animals. Infection through blood contamination of hypodermic needles, other fomites, and blood products has been reported.[576] Minor genetic variations occur among viruses from different geographic areas, forming four subtypes.[577] A similar disease of sheep in Spain is caused by a genetically distinct flavivirus.[578]

35.2.14.2 Clinical Signs

Sheep develop central nervous system (CNS) disorders. Infection in horses often is asymptomatic.[579] The initial clinical signs of louping ill include fever, anorexia, depression, constipation, and generalized muscular tremors. The ensuing signs are characteristic of CNS disease and include ataxia, conscious proprioceptive deficits, head tremors, hypermetria, and hyperexcitability. The hypermetria results in a characteristic “bunny hopping gait,” which gives the disease its name. Further progression of clinical signs is associated with cerebrocortical dysfunction; these signs include head pressing, hyperesthesia, recumbency, convulsions, coma, and death. Survivors have residual neurologic deficits. The duration of the illness is approximately 12 days.

35.2.14.3 Clinical Pathology

Both hemagglutination inhibition and complement fixation tests can be used to detect virus in infected animals.[576] High levels of virus-specific IgG and IgM can be detected in the cerebrospinal fluid (CSF) of affected animals.[580] Viremia peaks at approximately 3 days after inoculation and disappears by 7 days. Because animals usually are not viremic at the time the nervous system lesions develop, virus recovery is best done from the brain or spinal cord. Isolation of the louping ill virus from the CSF is difficult.

35.2.14.4 Pathophysiology

Ticks become infected when feeding on a viremic host. The virus survives in the salivary glands of the tick and can overwinter here, being transmitted to a new host when the tick becomes active the following year.[576]

After inoculation into susceptible sheep, the louping ill virus migrates into the regional lymph nodes and spleen and then replicates. Viremia occurs 6 to 20 days after the invasion of the lymphatic tissues.[571] Viral replication in the brain causes nonsupportive inflammation and neuronal degeneration.[571] Rapid antibody production is associated with recovery.[581] Concomitant infection of sheep with the agent of tick-borne fever *(Erlichia phagocytophila)* results in a greater level of viremia and increased mortality from the louping ill virus.[582]

35.2.14.5

Epidemiology

Louping ill principally affects yearling sheep in the spring. Maternal immunity wanes when lambs are about 3 months old. Infection develops weeks to months after sheep have been placed on pastures infected by *Ixodes ricinus*. In any outbreak the prevalence of clinical louping ill is low, but the seroprevalence of antibodies in adult sheep in endemic areas is high, indicating a continuous, low-level exposure to the virus, and many animals are asymptomatically affected. Factors such as climate, tick population, and immune status of the flock all play a role in the severity of an outbreak.[576] The case-attack rate may reach 60% of the population, whereas the mortality rate is low, rarely exceeding 15%. The degree of susceptibility of neonatal lambs and adult sheep is similar. Adults tend to be more heavily parasitized by the host ticks and thus play a major role in virus survival and transmission.[583] Pigs, cattle, horses, and red deer also become infected with the virus and can develop similar clinical disease. The seroprevalence rate of the virus in horses from one endemic area was 10%.[579] Milk from infected goats can reach titers high enough to infect suckling kids.[584]

Sylvatic cycles of virus transmission occur in which viral amplification takes place through certain wild mammals and red grouse.[570,585,586] The hare, in particular, appears to play a major role in the propagation and persistence of virus in the red grouse population.[587,588] Certain other small mammals, such as field voles, however, do not have a role in this cycle of virus persistence.[589] In the case of grouse, it has been demonstrated that the host can be infected by ingesting the infected tick, rather than by being bitten by the tick.[590]

994

995

Mild occupational infections can occur in shepherds, veterinarians, and laboratory workers who cultivate the virus. The louping ill virus probably is maintained on pastures through infected sheep because grouse populations become unstable and die out whenever the virus is introduced.[591] The high incidence of louping ill in the spring and summer months probably corresponds to the peak activity of ticks. The virus may persist for long periods in the arthropod vector, but it is unclear if transovarial transmission of the agent occurs. *Ixodes ricinus* is a three-host tick with a life cycle of 3 years. The ticks do not walk, and dissemination over a range requires animal transport. After a blood meal, the tick molts and then rests on vegetation until the next meal, approximately 12 months later. The activity of the ticks tends to increase greatly in the spring whenever the ambient temperatures are above 7°C (43°F).

35.2.14.6

Necropsy Findings

Gross lesions are absent at necropsy. The histologic lesions of louping ill include perivascular cuffing with mononuclear cells and neutrophils, gliosis, neuronal necrosis, and mononuclear cell meningeal inflammation.[592,593] Microscopic lesions are most severe in the Purkinje cells, the motor nuclei, and the ventral horn cells. The forebrain is spared.[594] Virus in tissue can be detected by virus isolation, IHC, and RT-PCR.[576,595,596]

35.2.14.7 Prevention

There is no treatment for louping ill encephalitis, but supportive care should be provided.

A formalin-inactivated vaccine given in the last trimester has been recommended for preventing louping ill.[597] A single dose of the vaccine provides responses that are protective for at least 2 years. Colostral antibody titers higher than 1:40 are considered protective.[583] Other methods of preventing the disease include frequent acaricidal dipping of sheep and clearing of pastures to reduce the population of infected intermediate hosts.

Louping ill has not been detected in the United States, but it is a reportable disease. Any suspicion of this disease should be reported to state and federal authorities. The disease also has a zoonotic potential; infection of humans can occur through tick bites, infected sheep or goat milk, or fomites.

35.2.15 RABIES

CHRISTINE BERTHELIN-BAKER

LISLE W. GEORGE

35.2.15.1 Definition and Etiology

Infection with rabies virus results in severe and usually fatal neurologic disease. Most mammals are susceptible and are infected through bites from other animals during or near the clinical phase of illness. The rabies virus and other highly neurotropic “rabies-related” viruses belong to the genus *Lyssavirus,* family Rhabdoviridae. (bullet-shaped RNA viruses). Wildlife provides a natural reservoir for rabies, and each rabies strain is maintained in particular reservoir host(s). Although they can readily cause rabies in other species, wildlife-adapted strains of rabies usually die out when passed into species to which they are not adapted. Other, “rabies-related” lyssaviruses can cause a neurologic disease identical to rabies. They include the Lagos and Duvenhage viruses of bats in parts of Africa, the Mokola virus of rodents and shrews in Africa, and the European and Australian bat lyssaviruses.[598–600]

35.2.15.2 Clinical Signs

Livestock cases of rabies have been reported mostly in cattle and occasionally in horses, sheep, and goats.[600,601] Rabies should be included in the differential diagnosis of any unexplained acute, rapidly progressive encephalitis, especially in the presence of autonomic instability, dysphagia, hydrophobia, paresis, or paresthesia.[600,602,603] The incubation period ranges from a few days to 6 months, depending on the pathogenicity of the inoculum and the distance from the site of inoculation to the brain. The shortest incubation periods are seen in animals bitten on the head, whereas the longest incubations have been reported after bites on the extremities of the pelvic limbs.

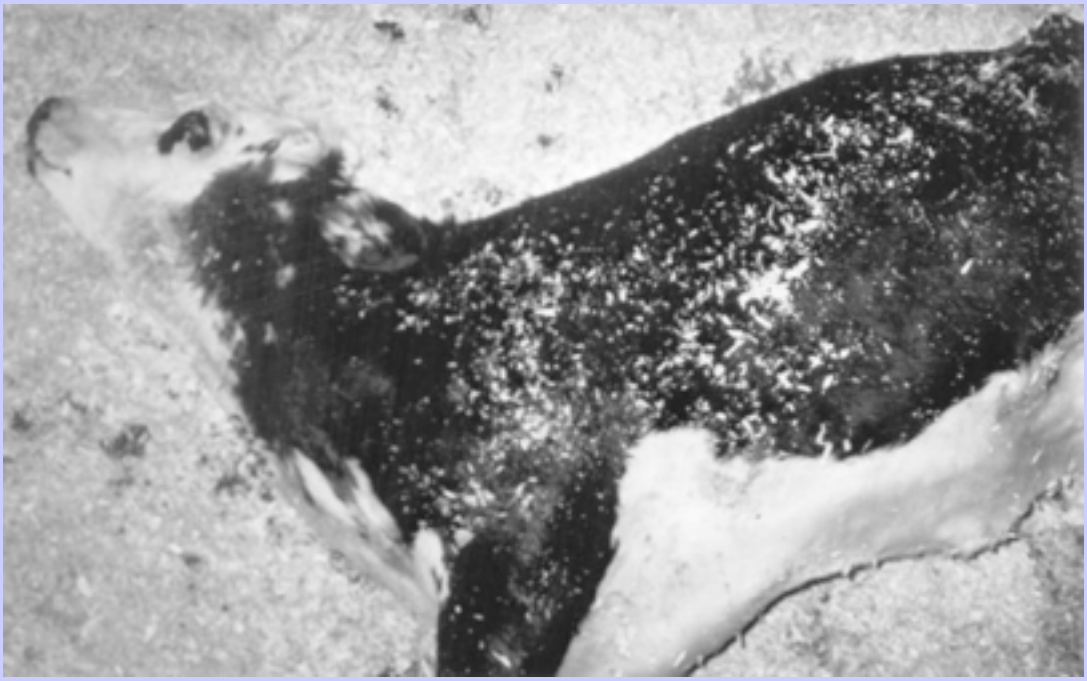
The disease is usually fatal after a clinical course of 1 to 8 days. Occasionally, an animal may be found dead without any previously observed clinical sign. Early clinical signs of rabies in livestock may be nonspecific sensory and behavioral changes, including anorexia, restlessness, depression, separation from the herd, and mild ataxia. Rumination may stop. Horses often appear colicky. Affected animals may repeatedly attempt to mount inanimate objects or show regional paresthesia with pruritus. Rubbing of the pruritic area results in

loss of hair or wool and skin ulcerations. As the disease progresses, animals may become hyperexcitable, fearful, or enraged *(furious rabies)* or mentally depressed *(dumb rabies)*. Furious and dumb states may alternate in the same animal. Cattle rabies frequently manifests as dumb rabies with flaccid paraparesis, tetraparesis, and tetraplegia *(paralytic rabies)* as the disease progresses.

In an experimental study, all cattle and sheep infected with the rabies virus exhibited excessive salivation and behavioral changes, and the majority also displayed tremors, bellowing, aggression, hyperesthesia, and pharyngeal paresis/paralysis.[600] Tetraplegic animals may show frantic motor activity of the legs and bellow when stimulated. Animals with dumb rabies are depressed, inappetent, and usually febrile (>39.4°C [103°F]) and may have a drooped head and neck, ptosis, flaccid facial musculature, profuse salivation, yawning, repeated nibbling motions with the lips, tenesmus, paraphimosis, odontoprisis, head pressing, circling, wide-base stance, difficulty rising, and falling episodes. Other clinical signs associated with dumb rabies include flaccidity of the tongue, tail, anus, and urinary bladder and blindness, strabismus, and nystagmus.

The first clinical sign of paralytic rabies in horses may be an unexplained ataxia or shifting leg lameness, soon followed by paraparesis or paraplegia.[604] Spinal reflexes and tone in the affected limbs may be decreased or absent. Most affected animals become recumbent in 3 to 5 days. Initially the recumbent animal may be able to eat and drink with help, but it soon becomes anorectic and develops encephalopathic signs, followed by coma and generalized seizures[605,606] (Fig. 35-4).

Fig. 35-4 Ten-month-old mixed-breed calf with terminal rabies virus encephalitis. The calf is comatose and showing opisthotonos.



995

Table 35-5 Occurrence of Particular Clinical Signs of Rabies in Horses

Clinical Signs	Frequency of Occurrence
Ataxia, paraplegia	11/21
Lameness	5/21
Pharyngeal paralysis	2/21
Recumbency	21/21
Colic	2/21
Hyperesthesia	17/21
Tail and anal paralysis	12/21
Fever	11/21

From Green S et al: Rabies in horses: 21 cases, *J Am Vet Med Assoc* 200:1133, 1992.

Regardless of the clinical manifestations, rabies is rapidly progressive and fatal disease leading to cardiorespiratory failure, and death usually occurs within 10 days. In all disease forms of livestock, the clinical signs rapidly worsen over 1 to 3 days, until the patient becomes recumbent and comatose. Animals may develop a pharyngeal-laryngeal paralysis resulting in stertorous breath sounds, inability to drink (thus the common name of "hydrophobia"), and accumulation of frothy saliva at the commissures of the lips.[607]

One summary of 21 cases of rabies in horses enumerated the frequency of particular clinical signs seen as the presenting complaint (Table 35-5). Rabies can only be differentiated from other encephalitic disorders by specific postmortem tests or virus isolation, which is usually not possible before death occurs. In horses the clinical signs of rabies often are indistinguishable from other encephalopathies, such as hepatoencephalopathy, leukoencephalomalacia, togaviral encephalitis, equine herpesvirus type 1 (EHV-1), protozoal and other meningoencephalomyelitides, and space-occupying masses. In ruminants, rabies may resemble herpesv.irus, thromboembolic meningoencephalomyelitides, nervous ketosis, grass tetany, polioencephalomalacia, nervous coccidiosis, or even focal spinal cord or peripheral nerve diseases. Most horses die of fatal encephalopathy within 5 days of the onset of signs; but cases lasting as long as 14 days have occasionally been observed.[608]

35.2.15.3

Clinical Pathology

There is no valid antemortem test to diagnose rabies in livestock. Rabies usually remains immunologically and serologically silent throughout the incubation and clinical phase of the illness.[244] Clinicopathologic tests are not specific for rabies but may help rule out other, more common diseases. The CSF may be normal or may show moderate mononuclear pleocytosis (5 to 30 cells/μL) and increased protein (60 to 200 mg/dL), occasionally with neutrophils, eosinophils, or xanthochromia reported.

35.2.15.4

Pathology and Postmortem Diagnosis

Rabies causes a nonsuppurative meningoencephalomyelitis. Microscopic changes include brain edema, meningeal congestion, focal areas of hemorrhage, perivascular cuffing, gliosis, neuronophagia, and neuronal degeneration. These changes are most severe in the dorsal root ganglia and can be seen in most CNS regions.

A definitive diagnosis of rabies may be based on the finding of Negri bodies (not always present, especially in cases euthanized early in the disease course) or through a positive direct or indirect fluorescent antibody (DFA, IFA) test conducted on fresh smears of CNS tissues (thalamus, hippocampus, brainstem, pons, medulla, cerebellum).[609–611] If these tests are negative or inconclusive and there has been human exposure, additional testing can be done using intracerebral inoculation of mice with CNS tissue from the suspect case. An antigen-capture enzyme immunodiagnostic technique has been developed for salivary gland specimens, to capture antigen onto solid phase using purified polyclonal antibodies. The specificity and sensitivity of this method are similar to the direct immunofluorescence test, but it has not gained widespread clinical use in the United States.[609] The DFA test on brain tissue has become the standard by which the value of other rabies tests is evaluated.[610] In cases of human exposure, the local public health parties should always be contacted before sample collection and submission. The diagnostic pathologist will usually accept the refrigerated head (or even whole body for small animals and bats), or refrigerated brainstem and cerebellum collected through the foramen magnum in mature cattle and horses. Care should be taken to prevent any human exposure to body fluids and CNS tissue of any animal with rabies on the list of differential diagnoses, especially in areas where rabies is known to be present in any domestic or wildlife species; open wounds or small healing sores may provide portal of entry for the rabies virus.

35.2.15.5

Pathophysiology

The structure of the rabies virus capsid proteins is similar to that of the neurotoxins of cobra venom and acetylcholine.[612] After subcutaneous or intradermal inoculation, the rabies virus replicates locally. After several days, it binds to the acetylcholine (and other) receptors of the peripheral nerves and then migrates retrogradely to the CNS through peripheral nerves, spinal rootlets, and the spinal cord. After entry into the nerve cell rootlets, the virus travels to the brain along nerve tracts and into CSF. From there it spreads centrifugally along the rootlets of the cranial nerves to the salivary glands and the nasal epithelium. Shedding of the virus in the nasal secretions and saliva may precede the onset of clinical signs but not the presence of virus in the brain, where it needs to replicate before it can reach the salivary and nasal secretions. Therefore, whenever an animal bites a person, the attacking animal can always be sacrificed and tested for the potential of rabies virus transmission, and it not necessary to wait for disease progression before testing an animal for rabies, as recommended earlier when Negri bodies were the main diagnostic test for rabies. In humans, most cases become apparent within 1 to 3 months of infection, but up to 10% of cases have had incubation periods in excess of 6 months, extending to several years in rare cases.[598] The rabies virus replicates in the cell bodies (gray matter) of the CNS. Dysfunction of these neurons results in behavioral changes and variable abnormalities of the cranial and the peripheral nerves, with multifocal loss of lower motor neuron and autonomic function. Death results from cardiorespiratory paralysis as the virus infects the brainstem medullary centers.

35.2.15.6

Epidemiology

Rabies is a reportable zoonosis that has been detected worldwide, with some exceptions (especially islands). It does not presently occur in Scandinavia, United Kingdom, Ireland, Australia, New Zealand, or Iceland.[598] The disease is endemic in other parts of the world, including the United States, Canada, and Europe, but remains epizootic in Central and South America, Africa, and parts of Asia, especially where a tropical climate and a high population of infected feral mammals favor viral propagation and transmission.[599,601] The rabies virus is shed in the saliva and does not survive when dried or exposed to ultraviolet (UV) light. The most common method of viral transmission to domestic animals is through the bite of an infected feral or wild mammal. Humans and laboratory animals have also developed fatal infections after respiratory exposure to viral aerosols. Low levels of rabies virus are also shed in the milk of infected animals and may occasionally infect offspring nursing infected dams.[613,614] Laboratory animals, foxes, and skunks also can be infected experimentally by ingestion of infected tissues from rabies cases.[613,614] The consumption of thorny bushes may also have caused horizontal transmission of rabies in an outbreak in African Kudu.[600] In the United States, survival of the virus in the wild may depend on cycling of infections in skunks, bats, or raccoons, which also are common sources of livestock infections.[615,616]

996

997

Certain strains of rabies virus have low virulence in skunks and bats, resulting in asymptomatic carriers serving as reservoirs. The rabies virus is also transmitted directly among bats through aerosols in caves. The bats may die off from rabies during periods of high viral contamination. In the United States the most common wild reservoirs are foxes in Alaska and along the border of Mexico, raccoons in the East, and skunks in the central and western regions.[601] Mandatory vaccination of dogs has virtually eradicated canine rabies from developed countries, where rabies transmission from domestic dogs to livestock is rare.[598,617] Island nations have been able to remain free of rabies by imposing a 6-month quarantine on imported dogs and cats. In South America, rabies outbreaks in cattle often result from vampire bat bites, causing up to 50,000 cattle deaths annually. Human rabies cases may result from bites inflicted by infected pets, feral dogs and cats, bats, or wildlife. Cases resulting from contact with infected cattle or horses are rare.[601,617,618]

Animal rabies cases are most common in late summer, possibly because wild animals give birth to offspring during the early spring, and young animals become infected and then spread the disease as they expand into new territory under pressure from selective forces (e.g., predation, starvation, hunting).

The various strains of rabies virus are maintained in different hosts. Serial passage of virus from field cases (“street rabies virus”) into laboratory animals can produce a modified, “fixed virus” with loss of virulence for the field hosts and increased virulence for the laboratory species. Such fixed strains have been used in the preparation of vaccine viruses.

35.2.15.7

Prevention

Although widespread rabies vaccination of livestock is neither economically feasible nor justifiable on public health grounds, vaccination of valuable livestock, or animals that travel or are in regular contact with humans (e.g., petting zoos, animal shows) should be considered, especially in or near rabies epizootic areas. A list of licensed rabies vaccines for the protection of animals against rabies is regularly updated by state veterinary authorities.[619]

The disposition of livestock that have been bitten by rabid animals depends on the animal's vaccination history, local and national regulations, and the value of the bitten victim. In the United States and Canada, the disease must be reported to the state public health department. Management of exposed livestock must be coordinated with public health officials. Any livestock bitten by a wild animal should be considered to have been exposed to rabies, regardless of the availability of the biting animal for testing. If a bitten horse had been vaccinated before the bite, it should be revaccinated immediately and kept under observation for 90 days. Other exposed, unvaccinated animals with a low economic value should be euthanized, or if the animal is very valuable, the bite wound may be washed with copious amounts of water and iodine or quaternary ammonium disinfectants, after which the animal should be quarantined for at least 6 months and the brain examined if it dies.[619,620]

Vaccination of animals shortly after rabies virus infection is not recommended because it is less effective than prophylactic vaccination. In one study, postinoculation vaccination of experimentally infected sheep had no effect on the incubation period, clinical signs, or mortality rate. Moreover, the antibody titers of the vaccinated animals had no predictive value for protection.[621,622] Whenever human exposure to rabies virus is suspected, the suspected animal must be euthanized and its brain examined for evidence of infection. A vaccinated or valuable animal may be quarantined for 6 weeks under veterinary supervision, and the brain must be examined if it develops clinical signs suggesting rabies during that period. The World Health Organization (WHO) publishes and regularly reviews its recommendations for vaccination and prophylaxis in humans after exposure or suspected exposure to the rabies virus.[599]

Control of rabies by immunization of susceptible wildlife using baits containing modified live vaccines has been successful in certain cases.[601,618,623,624] Such approaches may provide a means for large-scale immunization of wildlife or feral animal populations for eventual eradication of the disease.

35.2.16 SPORADIC BOVINE ENCEPHALOMYELITIS (BUSS DISEASE; POLYSEROSITIS; *CHLAMYDIA PECORUM* INFECTION)

Sporadic bovine encephalomyelitis (SBE) is caused by *Chlamydia pecorum,*[625] which produces a disseminated vasculitis and serositis. The disease was first reported in the United States in 1940.[626] A similar but not identical viral disease occurs in cattle in Australia and has been named “bovine ephemeral fever.”[627–630] SBE occurs in Czechoslovakia, Hungary, and Japan.[631–634] Nonsuppurative meningoencephalomyelitis also has been described in a study of cattle in Switzerland; a variety of pathologic patterns were found in those animals, and neither chlamydiae nor other common neurotropic organisms (rabies virus, Borna disease virus, tick-borne encephalitis virus) were identified as etiologic agents.[635] Outbreaks of SBE are rare, but the case-attack rate in an epizootic ranges from 5% in adults to 25% in calves. The mortality is highest in calves and approximates 31% for all age-groups.[636]

Infected cattle shed the organism in urine, feces, nasal secretions, and milk. It also can be found in the feces of asymptomatic calves exposed to clinically affected herdmates. However, the most common mode of transmission of the chlamydial agent is unknown. The agent tends to remain endemic on a single farm, and sporadic outbreaks of disease may occur only on those premises. The pattern of these outbreaks varies, from a few cases annually to acute, recurrent epizootics with high case-attack rates that subside after 3 to 4 weeks. Sheep and goats are resistant to the bovine agent.

35.2.16.1

Clinical Signs

Affected animals show signs of a multisystemic disease. The initial clinical signs in cattle are fever (39°C to 41.5°C [102.1° F to 106.7°F]), anorexia, depression, and stiffness. The cattle also may show signs of a respiratory disease characterized by nasal discharge, dyspnea, and cough. These animals occasionally have a painful response to percussion of the hoof, as well as swelling of the coronary band or polyarthritis and tenosynovitis.[626] Auscultatory abnormalities may include high-pitched wheezes and crackles over the lung fields or pleural and pericardial friction rubs. Because of the fibrinous peritonitis and pleuritis, the clinical signs in some affected animals may resemble those of hardware disease. These animals may grunt or groan when sudden pressure is applied to the xiphoid region. Some animals may respond to soft percussion of the xiphoid region by striking or kicking at the examiner. There is an initial diarrhea. Progression of the disease is related to development of the meningoencephalitis and is characterized by ataxia and conscious proprioceptive deficits, circling, head tilt, opisthotonos, hyperesthesia, stiff neck, convulsions, and coma. Animals may die after 4 to 10 days.

997

998

35.2.16.2

Diagnosis

The detection of elementary bodies in the exudate cells of pleural and peritoneal effusions is highly suggestive of SBE. The chlamydial agent can be cultured from the blood and body fluids of early infections in guinea pigs inoculated intraperitoneally with fresh tissue specimens and held for 6 to 7 days. Inoculation of embryonated eggs is a less sensitive diagnostic technique than animal inoculation. The causative organism has been identified as a distinct species, *Chlamydia pecorum,* by means of DNA analysis, immunologic assays, and serology.[635]

35.2.16.3

Pathogenesis and Pathologic Lesions

The mode of infection and the genesis of pathologic lesions are unknown in natural cases. Growth of the chlamydiae in the arteriolar endothelium causes vasculitis, hemorrhage, edema, and accumulation of fluid in the body cavities. Diffuse fibrinous pleuritis, peritonitis, and meningitis also are seen. Microscopic changes include perivascular mononuclear cell infiltration and neuronal degeneration. The lesions all are composed of networks of neutrophils and mononuclear cells enmeshed in fibrin. Some of the inflammatory cells contain elementary bodies.

35.2.16.4

Treatment

Early cases of SBE can be treated with oxytetracyclines (20 to 50 mg/kg/day for a minimum of 7 days). Efficacy is indicated by a reduction of fever within the first 24 hours of treatment. The chlamydial agent is also susceptible to penicillin and erythromycin, but the clinical efficacy of these drugs is unknown.

35.2.16.5

Control

There are no known effective control measures for the prevention of SBE. The chlamydial agent is susceptible to a number of disinfectants, including 2% sodium hydroxide (NaOH), 5% cresol, and 0.3% quaternary ammonium compounds.

35.2.17 *MORBILLIVIRUS* ENCEPHALOMYELITIS OF CATTLE

A nonhemagglutinating paramyxovirus *(Morbillivirus)* has been isolated from a calf with encephalitis. The disease was first described in Germany, but subsequent cases have been identified in Switzerland.[637] The German *Morbillivirus* organism is serologically related to the subacute sclerosing panencephalitis virus of humans but is unrelated to the parainfluenza virus of cattle. The clinical signs of *Morbillivirus* infection include pharyngeal paralysis, anorexia, salivation, hyperexcitability, intentional head tremors, aggressiveness, coarse muscle fasciculations, cutaneous analgesia, tonic-clonic seizures, dysphonia, and bellowing. The pathologic lesions include a diffuse, mononuclear cell encephalitis, perivascular cuffing with mononuclear cells, microglial cell proliferation, astrocytosis, neuronal loss, neuronophagia, and intraneuronal intranuclear (Cowdry type A) inclusion bodies.

35.2.18 BOVINE NECROTIZING ENCEPHALOMYELOPATHY

A neurologic disorder affecting Angus calves in Australia has been reported. Approximately 1% of the calves were affected, starting at 2 to 6 weeks of age.[638] The varied signs included nystagmus, strabismus, and wide-base stance with or without proporioceptive deficits, later progressing to recumbency with muscle tremors, bruxism, hyperesthesia, opisthotonos, and death 4 to 7 days after onset. Biochemical changes included increased hemoglobin concentration, neutrophilia, hyperglycemia, and elevated serum creatine kinase (CK) and aspartate transaminase (AST), but biochemical data were available for only two animals. At necropsy, small malacic foci 1 to 2 mm in diameter were observed in the medulla oblongata. Histologically, symmetric degenerative lesions were found in multiple brainstem nuclei, with variable involvement of the spinal cord gray matter and thalamus. The neuropil in affected areas exhibited pallor, edema, and spongiform change. There was central chromatolysis in neurons, cytoplasmic eosinophilia, nuclear margination, and necrosis. Mild inflammatory changes in the form of gliosis, infiltration of gitter cells, and endothelial hypertrophy were observed. Axonal spheroids were numerous.

This disease has been likened to Leigh's disease, inherited subacute necrotizing encephalomyelopathy, in humans. A heritable disorder was suspected because evidence indicated the herd was inbred, but pedigree analyses were not performed. Differential diagnoses included other heritable metabolic disorders, including lysosomal storage diseases, bovine cerebellar atrophy, and encephalomalacia caused by the endotoxin of *Clostridium perfringens* type D.

No treatment is currently available for bovine necrotizing encephalomyelopathy, but investigation into breeding practices and limiting inbreeding would be advisable.

35.2.19 MENINGITIS (SUPPURATIVE MENINGITIS; BACTERIAL MENINGITIS)

35.2.19.1 Definition and Etiology

Meningitis can occur either from direct extension of infectious agents into the calvarium or from hematogenous infection. Causes of suppurative meningitis include direct extension of pyogenic infections into the calvarium from infected skull fractures,[639] osteomyelitis from sinusitis or otitis, osteonecrosis caused by thermal cauterization during dehorning[640] or by improper placement of trephination holes, cribriform plate fractures, and extension from infected coccygeal vertebrae. In horses, septic meningitis is a common

sequela to surgical removal of progressive ethmoidal hematomas and also has been reported as a consequence of local spread of infections of the paranasal sinuses, nasal cavity, periocular tissues, and submandibular lymph nodes.[641]

Centripetal migration of *Cryptococcus neoformans* along peripheral nerve rootlets results in suppurative meningoencephalitis.[642,643] Other bacteria that can cause suppurative meningitis include *Streptococcus zooepidemicus* in foals and goats[644]; *Streptococcus suis* and *Streptococcus equi* in foals[645]; *Actinomyces* species in horses; *Escherichia coli, Pasteurella, Streptococcus, Staphylococcus pyogenes, Mannheimia,* and *Arcanobacterium (Actinomyces) pyogenes* in calves; and *Globicatella sanguinis* in lambs.[646–649] Embolic showers to the central nervous system (CNS) also occur in cases of left-sided endocarditis. *Pseudomonas aeruginosa* mastitis of cattle and goats may terminate with septicemia and meningitis. In adult animals, previous surgical procedures may result in sepsis and subsequent meningitis.[650] Management or environmental factors may predispose to outbreaks of meningoencephalitis within groups of animals, as occurs when inadequate colostrum is supplied to neonates, or when contamination of the water supply occurs, as reported in an outbreak of amebic meningoencephalitis in cattle.[651]

998

999

Suppurative meningitis of hematogenous origin is common in neonates (see Chapter 18). Gram-negative bacteria, *E. coli,* and *Salmonella* species are the dominant organisms involved in neonatal infections. One survey reported a 43% prevalence of septic meningitis in necropsied calves.[652] Deficient passive transfer of colostral antibodies to the neonate predisposes to hematogenous meningitis (see Chapter 53). *Mycoplasma mycoides* subsp. *mycoides* is a common cause of meningitis in goat kids. Underlying immunodeficiency disorders may predispose to the development of suppurative encephalitis in mature animals.[653]

35.2.19.2

Clinical Signs

The earliest clinical signs of meningitis are usually those of systemic illness, such as diarrhea, fever, and anorexia, accompanied by stiff neck and hyperesthesia.[654,655] Passive manipulation of the head and neck causes sudden extension and hypertonicity of the limbs. Slight tactile stimulation of the skin may result in strong spasmodic extension of the limbs, fasciculations of the underlying musculature, or even generalized frantic motor activity. The patient's behavior may vary from extreme depression to hyperexcitability or mania. Animals may display trismus and may vocalize when the head and neck are flexed. Tetraparesis, hyperreflexia, and a tendency to circle or fall toward one side may be noted. A subtle intentional head tremor often is observed in foals. Dysfunction of one or more cranial nerves may result in facial muscular tremors, nystagmus, facial palsy, blindness, anisocoria, or strabismus. These deficits are inconstant. Progression of the clinical signs is associated with a decreased sensorium, propulsive walking, coma, seizures, and status epilepticus. Evidence of infection elsewhere may be apparent, such as swollen joints, omphalophlebitis, or hypopyon.[647]

The clinical signs of purulent meningitis closely resemble those of metabolic encephalopathies, including hypomagnesemia, hypoglycemia (which may occur simultaneously with septic meningitis in neonates), and encephalomalacias (e.g., salt poisoning). The onset of clinical signs may be delayed in horses with *Cryptococcus neoformans* meningitis.[642]

35.2.19.3

Clinical Pathology

Septic meningitis should be differentiated from metabolic encephalopathies by measurement of the plasma concentrations of sodium, glucose, and magnesium and by laboratory evaluation of hepatic function. Diagnosis of meningitis is based on examination of the cerebrospinal fluid (CSF; for normal values, see Table 35-1). The CSF of animals with meningitis may be turbid and white to amber in color, may foam when shaken, and may clot. Xanthochromia may be observed in some specimens. The white blood cell (WBC) counts in CSF of calves with purulent meningitis are typically greater than 100 neutrophils/μL (mean count, 4004 WBCs/mL), and protein concentrations range from 20 to 270 mg/dL.[654] The differential cell counts in the CSF are either predominantly neutrophilic or mononuclear, with fewer neutrophils. The concentration of glucose in the CSF often is less than 50% of the corresponding concentration in the blood. Because of the lack of opsonic and bactericidal activity in the CSF, bacteria can proliferate to high titers and are often observed in Gram-stained smears of CSF. One study showed intracellular bacteria in 10 of 22 calves with meningitis.[656] Abnormalities in the blood are inconsistent and reflect secondary conditions such as septicemia, diarrhea, or overaggressive fluid therapy. These changes could include leukocytosis, left shift, toxic changes in the hemogram, hyperkalemia, respiratory acidosis, hypoglycemia, and hyponatremia or hypernatremia. Evidence of bacteremia and sepsis may be found in peripheral blood.

35.2.19.4

Pathophysiology

Because there is little bactericidal or opsonic activity in the CSF, animals are highly susceptible to meningeal infection by low numbers of bacteria. Bacterial proliferation in the CNS results in production of bacterial endotoxins, cytokines, and other products of inflammation that damage the neural parenchyma. Vascular sequelae of infection may include thrombotic or hemorrhagic infarcts. After several days, inflammation of the arachnoid trabeculae and choroid plexus can result in decreased CSF absorption and hypertensive hydrocephalus.[647]

35.2.19.5

Necropsy Findings

The meningeal vessels appear to be congested, and the meninges are swollen, opalescent, and petechiated. The CSF is cloudy or amber and may contain fibrin clots. In cases associated with bacteremia, a fibrinopurulent iridocyclitis may be observed. Microscopic changes of CNS tissues include infiltration by neutrophils and lymphocytes, endarteritis of the meningeal vessels, choroiditis, scattered leptomeningeal hemorrhages, and bacterial colonies around the blood vessels of the meninges and the brain parenchyma.

Concomitant pathologic lesions, including omphalophlebitis, septic arthritis, anterior uveitis, and panophthalmitis, result from dissemination of the septic process. These lesions may be helpful in differentiating meningitis from metabolic encephalopathies. When meningitis occurs secondary to trauma, the site of organism entry may be detectable. Fungal meningitis caused by *C. neoformans* often is accompanied by granulomatous lesions of the lips, nasal mucosa, and peripheral nerves.

35.2.19.6

Treatment

Treatment of bacterial meningitis is difficult, and the mortality rate is high. Early recognition and treatment are essential for adequate recovery. Antimicrobial sensitivity tests performed on isolates from CSF may

provide valuable information on ideal drugs. However, these tests frequently are unavailable because of the difficulty in isolating primary pathogens from CSF in most cases of purulent meningitis. Because prompt treatment of meningitis is critical, antibiotic therapy usually must be based on the Gram-staining characteristics of sedimented bacteria and the initial 24-hour cultures.

Domestic animals have a well-defined blood-CSF barrier, and antibiotics that reach high plasma concentrations may not necessarily reach bactericidal concentrations in the brain. To ensure an adequate antibacterial efficacy, antibiotic concentrations in the CNS should range from 10 to 30 times the minimum inhibitory concentration (MIC) of the infecting bacteria.[656–664] Antibiotics that are inherently bactericidal tend to produce superior responses compared with agents that are primarily bacteriostatic. The major factors influencing CSF penetration of an antimicrobial agent are the lipid solubility, degree of ionization, and molecular weight of the drug. In general, broad-spectrum drugs with a nonpolar basic character tend to have the greatest CNS penetration and efficacy for treatment of meningitis. Antibiotics tend to diffuse into CSF to a greater extent when it is inflamed. Box 35-1 shows the relative penetrability of antibiotics and antimicrobials into the CSF.

Antibiotic treatments should be administered by intravenous (IV) routes to attain maximum peak blood and CSF concentrations and should be continued for 14 days or longer. Table 35-6 presents the recommended dosages for each of the antibiotics.

999

Selection of antibiotics should be based on the results obtained from Gram-stained smears and cultures of the CSF or from other infected areas. Penicillin G is a polar acidic drug that has limited distribution into the CSF. Because of this and the predominance of gram-negative CNS infections in livestock, penicillin alone is a poor choice for initial therapy of uncharacterized purulent meningitis.[665–670] Nevertheless, administration of very high IV dosages of penicillin may be effective for the treatment of meningeal infections by highly susceptible bacteria such as *Streptococcus* or *Haemophilus* organisms. In these cases, low but therapeutic concentrations of the drug can be achieved in the CSF. In humans, IV dosages of 250,000 U/kg daily are required to achieve CSF penicillin concentrations ranging from 0.3 to 0.8 µg/mL.[665] For infections caused by gram-positive bacteria with intermediate susceptibility to penicillin, multiple daily IV dosages of ampicillin (15 to 20 mg/kg) may be useful.

Gentamicin

Tetracycline

Penicillin G

Kanamycin

Streptomycin

Neomycin

* Prohibited in food-producing animals in the United States.

Table 35-6 Recommended Drug Regimens for Treatment of Bacterial Meningitis in Livestock

Antibiotic or Antimicrobial Drug	Dose, Route, and Frequency	Indication, Comments
Trimethoprim-sulfadiazine	30 mg/kg sulfa PO twice daily	Staphylococci, *Klebsiella,* some coliforms; long-term medication; not for use during acute crises
Chloramphenicol*	100–200 mg/kg PO four times daily *or* 100–200 mg/kg IV six times daily	Staphylococci, streptococci, *Klebsiella, Actinobacillus, Corynebacterium,* some coliforms
Third-generation cephalosporins (moxalactam, ceftriaxone, cefotaxime)	40 mg/kg IV four times daily	Staphylococci, streptococci, coliforms, *Klebsiella, Actinobacillus, Bordetella, Salmonella, Pseudomonas, Corynebacterium;* expensive
Isoniazid	5–20 mg/kg PO two times daily	*Arcanobacterium pyogenes, Rhodococcus equi;* long-term oral therapy is indicated; combine treatments with penicillin, ampicillin, or erythromycin
Erythromycin (cattle only)	10 mg/kg IM two times daily	Streptococci, some anaerobes, *Arcanobacterium pyogenes, Rhodococcus equi;* do not administer to horses or small ruminants; give to cattle only for 3 days; expect severe muscular swelling
Penicillin G, sodium	22,000–240,000 IU kg slow IV four times daily	Some staphylococci, streptococci, anaerobes, *Pasteurella, Haemophilus, Arcanobacterium pyogenes, Rhodococcus equi;* rapid IV infusion may be acutely fatal to small ruminants
Ampicillin, sodium	15–20 mg/kg IV four times daily	Some staphylococci, streptococci, anaerobes, *Pasteurella, Haemophilus, Arcanobacterium pyogenes, Rhodococcus equi;* safer for small ruminants than IV penicillin G
Ticarcillin/clavulanate	44–50 mg/kg IV four times daily	Staphylococci, streptococci, anaerobes, *Pasteurella, Haemophilus, Actinomyces, Rhodococcus equi, Klebsiella,* coliforms
Tetracycline (100 mg/mL concentration)	6–12 mg/kg IV two times daily	Some coliforms, staphylococci and streptococci, *Pasteurella, Haemophilus, Actinomyces, Rhodococcus equi* limited spectrum of activity
Amikacin sulfate	6.6–7.5 mg/kg IV or IM two times daily	Coliforms, *Klebsiella, Pasteurella, Haemophilus*
Metronidazole*	22–25 mg/kg/day PO or IV	Anaerobes

Data regarding predicted susceptibility of bacteria to specific antimicrobials can be found in Prescott JF et al: *Can Vet J* 25:289, 1984.

IM, Intramuscularly; *IV,* intravenously; *PO,* orally.

* Use prohibited in food animals in the United States.

Meningitis caused by the Enterobacteriaceae should be treated with aminoglycoside antibiotics or third-generation cephalosporins. Although aminoglycoside antimicrobials are highly effective against gram-negative pathogens and are bactericidal, their efficacy for the treatment of purulent meningitis is diminished by their polar basic characteristics and low attainable CSF concentrations. The aminoglycosides used most often for the treatment of bacterial meningitis include gentamicin (3 mg/kg IV or IM three or four times daily) or amikacin (6.6 mg/kg IM three or four times daily).[671]

Because of the difficulties associated with aminoglycoside penetration into the CSF and antimicrobial resistance, intrathecal therapy with preservative-free aminoglycoside antibiotics has been recommended for gram-negative meningitis. Intrathecal or intraventricular gentamicin (1 mg daily in smaller animals, 0.05 mg/kg in larger animals) has been recommended for treatment of *P. aeruginosa* meningitis.[672] The safety of the procedure has been questioned, however, on the basis of reports of increased mortality in experimentally treated rabbits and in children with naturally acquired infections.[672,673]

1000

1001

The third-generation cephalosporins moxalactam, cefotaxime, ceftiofur, and ceftazidime have a high efficacy against gram-negative CSF pathogens and penetrate the blood-CSF barrier better than penicillins or aminoglycoside antibiotics.[674–676] They also are resistant to inactivation by the β-lactamases of the gram-negative bacteria and retain activity in purulent debris. Because of these characteristics, the cephalosporins often are preferred over the aminoglycoside antibiotics for treating gram-negative CNS infections. The recommended dosage for ceftiofur is 5 to 10 mg/kg IV or IM one to three times daily.[647] Fluorinated quinoline antibiotics have a reproducible penetration into the CNS. In laboratory animals, data show that the drugs reached CSF concentrations of 4 to 8 mg/L.[677] The recommended dosage of enrofloxacin for bacterial meningitis is 5 mg/kg IV twice daily. Experimental animals have been given dosages as high as 50 mg/kg for some types of infections.

When the quinoline antibiotics or third-generation cephalosporins are too costly, trimethoprim-sulfonamide (TMS) combinations may be an effective substitute for horses.[678–682] TMS has good penetration into the CSF and may be useful for horses, foals, and preruminant calves, lambs, and kids. The drug is not useful for treating ruminating animals. In the ruminant the half-life of parenteral trimethoprim is short (60 minutes) compared with that of sulfonamide (11 hours). The short half-life of trimethoprim in the ruminant largely results from ruminal excretion and inactivation of the drug. TMS has a higher efficacy in preruminants and horses because the half-life of trimethoprim is significantly longer than in the adult ruminant. The recommended dose is 5 mg/kg/day based on IV trimethoprim given two or three times daily.[647] Combinations of ampicillin with third-generation cephalosporins or TMS may broaden the antibiotic spectrum.

Patients should be observed closely for the first 3 weeks after the start of therapy because clinical improvement is associated with decreased permeability of the blood-CSF barrier and reduced CSF concentration of the chemotherapeutic agent.[646,665–667] Bacteria remaining in the CNS may regrow as a result of the lowered antibiotic concentration, and clinical signs of meningitis may return after a period of initial improvement.[667] This recurrence of signs after 3 to 4 days of seemingly successful therapy should indicate the necessity for an increased antibiotic dosage or a change in the type of antibiotic.

Although chloramphenicol has a nonpolar character and good lipid solubility, it is bacteriostatic and does not reach bactericidal concentrations in the CSF. Its efficacy for the treatment of gram-negative meningitis is

limited. Because of this and the current regulatory restrictions imposed by the U.S. Food and Drug Administration (FDA), chloramphenicol cannot be recommended for the treatment of purulent meningitis in large animals, especially ruminants. The tetracyclines do not appreciably cross the blood-brain barrier and also cannot be recommended for the treatment of bacterial meningitis except for certain highly susceptible infections such as *Haemophilus somnus*.

Table 35-7 Suggested Anticonvulsant Drug Regimens for Treatment of Seizures in Horses and Cattle

Drug	Dose, Route, Frequency	Comments
Diazepam (Valium)	0.01–0.2 mg/kg IV every 30 minutes as needed to control convulsions	Effective for rapid control of status epilepticus; poor choice for long-term therapy because of cost and short plasma half-life
Phenobarbital	12–20 mg/kg IV initial dose, dilute in saline over 30 minutes 11 mg/kg PO once daily (horses)	Begin treatment in convulsive neonates with intravenous (IV) drips; for long-term administration, give orally; monitor trough plasma concentrations of phenobarbital Therapeutic concentrations range from 15 to 40 µg/mL
Pentobarbital	2–20 mg/kg IV (~2 mL/5 kg body weight); repeat every 4 hours as needed for control of status epilepticus; not good for long-term control of sporadic seizures	Must administer slowly and monitor depth of anesthesia carefully to prevent respiratory arrest; control of convulsions in adult horses and cattle often occurs at lower IV dosages; use IV catheter for repetitive administrations

Cryptococcal meningitis of horses has been treated by 100 to 150 mg of IV amphotericin B in 4000 mL of 5% glucose, repeated every 48 hours for 23 days. One horse improved with this treatment but relapsed. Flucytosine (Ancobon, Hoffman LaRoche) was recommended as an alternative treatment.

Concomitant administration of dexamethasone sodium phosphate or an NSAID may improve recovery from purulent meningitis. The choice of steroid versus nonsteroidal drug has not been established for large animals. Supportive therapy for animals with suppurative meningitis should include protection from self-inflicted trauma, sedation, amelioration of pain, fluid therapy, and anticonvulsants.

Convulsions can be controlled by diazepam (Valium) or phenobarbital at respective IV dosages of 0.01 to 0.4 mg/kg[671] and 20 mg/kg (Table 35-7). For IV phenobarbital, the drug should be diluted in saline and administered slowly over 30 minutes. Repeated doses (1 to 9 mg/kg) are given three times daily.[683] After administration of 9 mg/kg to horses, plasma concentrations of phenobarbital range from 11.6 to 53 µg/mL.[684] Phenobarbital distributes slowly in the fat deposits. Because this could lead to drug accumulation, the trough drug concentrations should be measured frequently. The maximum desirable trough phenobarbital concentration is 40 µg/mL, and the minimum therapeutic level is 15 µg/mL.[683,685] After initial sedation, long-term control of convulsions in horses can be maintained by oral diphenylhydantoin (2.8 to 16 mg/kg three times daily) or IV phenobarbital (11 mg/kg once daily).[685–687] The trough plasma concentration of diphenylhydantoin should also be measured repeatedly during continuous drug therapy; the maximum

desirable trough level is 10 to 20 µg/mL,[686] and optimum plasma concentration is 5 to 10 µg/kg. Primidone is metabolically activated to phenobarbital. Because it is more expensive than phenobarbital, however, primidone is not usually administered to large animals.

The concentration of plasma immunoglobulins should be measured in neonatal patients with bacterial meningitis. Neonates with a plasma protein concentration less than 4.5 g/dL or an IgG concentration less than 500 mg/dL should be given 1 to 2 L of plasma from a normal adult.

1001

1002

Nonsteroidal antiinflammatory drugs (flunixin meglumine or phenylbutazone) are useful analgesics in animals with suppurative meningitis; Table 35-7 lists suggested dosages and routes of administration. Good nursing care is essential. Parenteral fluid therapy should be administered to animals that are unable to drink. Fluid dosages should be selected to replace insensitive water losses and existing deficits (40 to 80 mL/kg daily; balanced electrolytes). The blood pH, serum osmolality, and plasma concentrations of glucose, sodium, potassium, and magnesium should be closely monitored during the antimicrobial therapy and measured repeatedly in animals having seizures.

35.2.20 PITUITARY ABSCESSES

Pituitary abscesses occur sporadically in ruminants. *Arcanobacterium pyogenes* is the most frequently isolated bacterium, but *Corynebacterium pseudotuberculosis,* as well as *Streptococcus, Staphylococcus, Actinomyces, Bacteroides, Fusobacterium, Acinetobacter, Pasteurella, Pseudomonas,* and *Actinobacillus* species, occasionally have been isolated.[688] Pituitary abscesses are rare in horses.

The clinical signs of pituitary abscess occur suddenly and progress for 7 to 10 days before the affected animal dies.[688] The initial signs are ataxia, head-neck extension, wide-base stance, inappetence, depression, head pressing, and recumbency.[688–690] Most affected animals have asymmetric deficits of one or more cranial nerves, resulting in dysphagia, blindness, anisocoria, absent pupillary light reflexes, mydriasis, flaccid tongue, nystagmus, facial paralysis, facial hypalgesia, ventrolateral strabismus, or head tilt.[688,691] Approximately 50% of the affected animals have bradycardia (pulse rate <60 beats/min).

The CSF protein concentration in affected cattle ranges from 70 to 502 mg/dL, and nucleated cell counts range from 6 to 12,640/µL (6% to 84% neutrophils).[688] The antemortem diagnosis is based on the observation of bradycardia, blindness, and nonresponsive pupils in conjunction with evidence of pyogenic inflammation in the CSF.

Some authors have postulated that the infectious agent gains entry to the sella turcica hematogenously and then localizes in the rete mirabile, which is the complex of blood vessels encircling the pituitary gland.[688] A direct relationship exists between the complexity of the rete mirabile and the incidence of pituitary abscessation in different mammals. The horse and dog lack a well-defined rete and correspondingly have a low risk for developing a pituitary abscess, whereas the situation is reversed in cattle. One study reported that 55% of cattle with a pituitary abscess had pyogenic foci in other organ systems or in the sinuses, teeth, or soft tissues of the face,[688] indicating that the abscesses may result from a retrograde bacterial embolization through branches of the facial veins.

Ataxia is caused by interruption of extrapyramidal motor nuclei in the brainstem by the expanding abscess. Extension of the abscess into the communicating retroorbital rete may result in exophthalmos. Extradural extension of the abscess along the brainstem causes sequential loss of the cranial nerve function, with the

nerves closest to the pituitary gland the first to become dysfunctional. Bradycardia may be caused by interference with diencephalic cardioacceleratory centers. In animals that survive for several weeks, the abscess may extend into the dura mater and cause a suppurative meningoencephalitis.

Animals ranging in age from 9 months to 12 years have been affected, but most cases occur between 2 and 5 years of age.[692] Pituitary abscess appears to have a slightly increased prevalence in castrated and intact males.[688] A high incidence of pituitary abscessation has been related to infections that developed in bulls after insertion of a nose ring. Prophylactic administration of penicillin and attention to aseptic procedure during insertion of the ring can reduce disease incidence.[690] Because of the high mortality rate associated with pituitary abscesses, treatment usually is not attempted.

35.2.21

BRAIN ABSCESSES

Because of the high incidence of strangles, *Streptococcus equi* is the most common cause of brain abscesses in horses.[693] *Arcanobacterium pyogenes* is a common cause of brain abscesses in cattle by means of extension of a sinus infection through the calvarium. Brain infections of cattle with *Bacteroides* species have also been reported.[694] The neurologic dysfunction caused by brain abscesses typically has a slower onset and is more asymmetric than that caused by meningitis, probably because most abscesses initially are extradural. However, acute onset of signs also can occur.[693] Forebrain abscesses compress the cerebral cortex, causing a caudal displacement of the brain and functional loss of one or both occipital lobes. Because of the high proportion of crossed fibers in the optic nerve decussation, unilateral cortical abscesses result in vision loss in the contralateral eye. Increased CNS compression by the mass results in ipsilateral mydriasis caused by interference with the oculomotor nerve. Further increases in the size of the lesion cause more generalized cortical signs, including blindness, propulsive walking, circling, head tilt (toward the lesion side), depression, coma, head pressing, or sudden unexplained mania. Abscesses at the base of the brain may cause additional abnormalities of cranial nerve function, including vestibular disease (Figs. 35-5 and 35-6).[693] Ophthalmoscopic examination may reveal papilledema in the ipsilateral eye. Advanced imaging studies, such as computed tomography (CT) and magnetic resonance imaging (MRI), may be helpful for antemortem diagnosis when these modalities are available.[695,696]

Fig. 35-5 Severely obtunded bull that developed a brain abscess from extension of a frontal sinusitis. The abscess extended to the base of the brainstem and affected cranial nerves V and XII, resulting in dropped jaw and tongue paralysis. The bull also was severely depressed, blind, and ataxic and had facial analgesia.

1002

Fig. 35-6 Head pressing in a pony caused an abscess in the right cerebral hemisphere. Courtesy Dr. R.H. Whitlock.

In later stages, animals may assume lateral recumbency and display a decerebrate posture characterized by hypertonicity, hyperreflexia, opisthotonos, coma, and convulsions. At this stage the disease is difficult to differentiate from septic meningitis. CSF findings in animals with brain abscesses are variable, ranging from normal to very abnormal, with high protein concentration and marked pleiocytosis.[693,697] Treatment of brain abscess includes antibiotics and supportive care (see Meningitis in this chapter). In one clinical report a brain abscess in a horse was localized with CT scanning and successfully drained through a craniotomy.[695]

35.2.22 MYCOTIC ENCEPHALITIS

Reports of a horse and a calf infected systemically with a phycomycete described recumbency and coma. Pathologic CNS changes consisted of cerebellar and occipital cortical infarction.[698,699] The CSF changes included a greatly increased Pándy test (for elevated CSF protein concentration) and an increased WBC count (79/µL). The cell population in the CSF was composed of 81% mononuclear cells and 19% neutrophils.

35.2.23 BRAIN TRAUMA

35.2.23.1 Definition and Etiology

Because of their size, behavior, and relatively thin calvarium, horses are more susceptible to head trauma than other livestock. Traumatic injuries of horses most often result from kicks, sharp blows, or falling over backward.[700] Blows to the poll of the horse, particularly associated with falling over backward, are very common and result in fracture or displacement of the basisphenoid, occipital, and petrosal bones and the basioccipital and basisphenoid sutures.[701–703] Young horses are particularly prone to this type of injury, probably because of their more fractious nature and tendency to react strongly to restraint, as well as to lesser strength of the immature skull.[703] The basisphenoid and basioccipital bones form a part of the foramen lacerum and the jugular foramen. Fractures around these foramina may result in dysfunction of CNs IX, X, and XII.[704] Hematomas form at the fracture site and extend into the membranous labyrinths and basilar areas of the brain, where they cause vestibular and occipital cortex dysfunction. Basilar region fractures carry a much more guarded prognosis than trauma at other sites.[703] Blows to the forehead result in depression fractures of the dome of the calvarium and trauma to the underlying cerebrum.

Skull fractures occur in cattle from blows to the top of the calvarium. Most skull fractures are located in the center of the frontal bones, where the internal and external plates of the frontal sinus are fused into a single-layer dorsal wall of the cranial vault. This position can be located on the skull as the imaginary cross found by intersecting lines drawn between the medial canthus of the eye and the horn of the opposite side. Injuries in this area compress the frontal and parietal lobes of the cerebral cortex. The pressure changes result in loss of sensorium, sensory deficits, blindness contralaterally, or convulsions.

In young goats and horned sheep under 4 to 6 months of age, the calvarium can be inadvertently opened by removal of excessive bone during disbudding or dehorning. In goats, cerebrocortical burns can occur from overapplication of a hot iron or caustic dehorning paste. Cortical necrosis caused by bacterial infections after dehorning of calves has also been described.[705]

35.2.23.2 Clinical Signs

The clinical presentation of cerebral trauma depends on the area of the brain damaged, the extent of the lesion, and the duration of the injury.[706] Lesions of the cerebral cortex and thalamus are characterized by variably altered mentation, circling, head pressing, pacing, aimless wandering, and cortical blindness (blindness with normal eyes, pupillary light reflexes, and oculomotor reflexes). Seizures also may result; however, occurrence of a seizure does not necessarily indicate a poor prognosis.[703] Compression of the midbrain results in decerebrate rigidity caused by loss of the reticulospinal tracts. In more severe cases of midbrain compression, abnormal breathing patterns may be observed, together with hyperreflexia, tetraplegia, and absence of pupillary reflexes. Compressive lesions of the mesencephalon in the region of the oculomotor nucleus result in mydriatic pupils on the ipsilateral side of unilateral brainstem lesions. Medulla oblongata compression is characterized by serial dysfunction of cranial nerves, severe disturbance of consciousness, and abnormal respiratory rhythm. Involvement of the long motor and sensory pathways to the limbs can occur with brain injuries at any level and results in ataxia and paresis, which may be worse on the

side contralateral to the injury in the case of cerebral cortex, thalamic, and midbrain injury, or on the ipsilateral side in the case of traumatic damage to the medulla or cerebellum.

Basioccipital fractures of horses result in asymmetric signs of vestibular disturbance, including horizontal or rotary nystagmus, ipsilateral ventrolateral strabismus, contralateral dorsomedial strabismus, head tilt, and contralateral blindness. Horses that remain ambulatory lean or circle toward the side of the lesion. Additional signs of this syndrome include dysphagia, facial paralysis, conscious proprioceptive deficits, recumbency, depression, and coma. Horses that are recumbent struggle violently. Fracture of the petrous temporal bone may cause profuse bleeding from the ipsilateral nares, external ear canal, and guttural pouch.

Brain trauma caused by overaggressive dehorning in goats results in depressed sensorium, loss of menace response, increased extensor tonus on the contralateral side, ipsilateral mydriasis, sluggish pupillary reflex, and loss of conscious proprioceptive responses. The clinical syndrome may be delayed by several days in cases of cortical burns or trauma caused by caustic paste and may be complicated by brain abscess or bacterial meningitis.

35.2.23.3

Pathology and Pathogenesis

The pathogenetic events leading to cerebral edema and increased intracranial pressure (ICP) are complex. Trauma to the head results in a variety of abnormal physical forces exerted on brain tissue, including 1003
acceleration-deceleration, shearing, compressive, tearing, and rotational forces.[706–708] The consequence of 1004
direct physical insult to brain tissue that occurs immediately on impact is considered *primary* traumatic brain damage.[707] Such physical insult results in axonal injuries that may be immediate (primary axotomy), such as axonal tearing, or occur many hours after the initiating event (secondary axotomy).[708] Trauma activates neuronal mechanoreceptors, causing cellular depolarization that spreads outward from the site of impact. Together with direct axonal injury, this may underlie initial signs of concussion, including loss of consciousness.[706,708] Processes that follow the initial mechanical trauma and further exacerbate injury are considered *secondary* brain damage.[707] Intracranial hemorrhage or loss of vascular integrity and cerebral edema occur after concussive blows to the head. Hemorrhage after head trauma may be epidural, subdural, subarachnoid, or intraparenchymal.[707] Displacement of the neural tissue is caused by cerebral swelling or hematoma formation. The increased pressure is transmitted to the CSF and interferes with normal vascular flow, resulting in cerebral hypoxia and interneuronal and intraneuronal edema. Diminution of cerebral perfusion results from a combination of increased ICP, disruption of the vascular architecture, and decreased systemic blood pressure. The net result is reduced oxygen delivery to the brain, a tissue that relies on aerobic glycolysis for the production of energy. Interruption of energy production within the brain results in failure of tissue homeostasis. Breakdown of the blood-brain barrier further contributes to brain swelling and loss of intracranial homeostasis.

In addition to gross damage to tissue, brain trauma results in a complex series of biochemical events that disrupt cellular integrity.[706,709] One of the most important is the depletion of adenosine triphosphate (ATP), the main energy store within neurons. This results in dysfunction of cell membrane ionic pumps, permitting influx of sodium (Na^{+}) and calcium (Ca^{++}) into the cell. Influx of these ions activates a number of secondary pathways within the cell, including the kinin, arachidonic, complement, and xanthine-oxidase pathways. Activation of these pathways results in the production of a variety of substances that are deleterious to cellular function, including oxygen free radicals, vasoactive mediators, cytokines, nitric oxide, excitatory

neurotransmitters, and enzymes. Together, these contribute to a destructive cascade of events that further damages cell integrity.[709]

When brain swelling becomes severe, the respiratory centers are depressed, resulting in hypoxemia and acidosis. The extra carbon dioxide diffuses into the brain, and water follows, which further swells the CNS. Acidosis and hypoxemia also worsen the vascular leakage and hypoxemia. Extreme swelling of the cerebral cortex results in herniation through one or more anatomic sites of the calvarium. Four forms of brain herniation have been described in large animals.[710] These include cingulate gyrus herniation ventral to the falx cerebri, herniation of parts of the temporal cortex ventral to the tentorium cerebelli (caudal tentorial herniation), caudal cerebellar vermis herniation through the foramen magnum, and herniation of the rostral cerebellar vermis ventral to the tentorium cerebelli (rostral tentorial herniation). Compressed tissue becomes hypoxemic and edematous. Compression of the CNS causes more hypoxia, prompting a dramatic and rapid deterioration.

35.2.23.4

Clinical Pathology

Clinical pathologic variables noted after head trauma include nonspecific changes consistent with a stress response, such as mild neutrophilia, lymphopenia, and hyperglycemia, as well as those resulting from systemic trauma, such as elevated serum CK.[703] Hyperglycemia has been associated with more guarded prognosis in people with head injuries, possibly from deleterious effects on cerebral vasculature.[711] In one study of horses that had head trauma, only elevated packed cell volume (PCV) was shown to be associated with a more guarded prognosis.[703]

Collection of CSF from the atlantooccipital cistern is generally contraindicated in head trauma, especially if signs of increased CNS pressure, uncontrolled hemorrhage from the ears or the nose, or dorsal sagittal sinus fractures are observed. Clinical signs that may suggest the presence of increased ICP include dull mentation (especially if this is worsening over time), mydriasis, blindness, or papilledema. The CSF changes that occur from traumatic injuries are characteristic. For the first 24 hours, blood is admixed evenly in the CSF. Iatrogenic hemorrhage from the tapping procedure can be differentiated from that caused by trauma because in the former case, the CSF is irregularly streaked with blood; CNS hemorrhage usually results in an even admixture of blood through the CSF. During the first 24 hours, the protein concentration and WBC count of CSF are elevated and are in the approximate ratio as that of peripheral blood. By 48 hours after the traumatic episode, the amount of blood in the CSF decreases, and when centrifuged, the cell-free CSF appears xanthochromic. WBC counts of the CSF are only marginally increased by 24 hours after hemorrhage, and the protein concentration may range from 500 to 1000 mg/mL (albuminocytologic dissociation). Thereafter, the protein concentration gradually decreases, and the xanthochromia disappears by 14 days after the acute hemorrhage. The number of mononuclear inflammatory cells gradually increases as parts of the CNS degenerate. The CK level of the CSF is elevated (10 to 100 IU/dL) for approximately 1 to 2 days after the acute traumatic episode.

35.2.23.5

Diagnostic Imaging

Radiography or more advanced imaging studies (CT, MRI) are the primary modalities for definitive diagnosis of skull fractures. It should be remembered, however, that significant brain trauma can occur in the absence of skull fracture and that this is a common situation. Radiography has the advantages of being widely available and relatively simple to perform, requiring restraint or only mild sedation in most situations.

However, false-negative findings are common, especially in cases where the bony lesion may be particularly difficult to identify, as with basilar bone fractures in horses.[703] While basilar fractures may be difficult to identify, other radiographic changes such as soft tissue densities in the tympanic bullae due to hemorrhage, or gas opacities adjacent to the basilar region, may support this diagnosis.[711a] CT is the technique of choice for the diagnosis of bony lesions and for acute intracranial hemorrhages, whereas MRI facilitates diagnosis of a variety of pathologic changes within the brain parenchyma. These advanced imaging techniques have limited availability, are costly, and usually require general anesthesia. Clinical findings and historical information may form the sole bases for diagnosis in many cases.

35.2.23.6

Treatment

The treatment of brain trauma remains one of the most controversial areas of clinical neurology in all species. Opinions differ widely and evidence in the scientific literature is often contradictory. Treatments that show promise in rodent models of head injury often are disappointing in clinical trials.[711b] Successful treatment depends largely on early recognition and initiation of therapies that maintain cerebral and whole body homeostasis. General medical principles for treating CNS trauma include (1) establishment of proper respiratory function, (2) support of blood pressure and maintenance of cerebral perfusion and oxygenation, (3) control of seizures, (4) nutritional and fluid support, and (5) protection from decubitus and self-inflicted damage. Many treatment modalities recommended for head-injured large animals are based on anecdotal reports and are not supported by rigorous scientific studies. It is reasonable, however, to apply the principles of head trauma management established in other species, including humans, to the management of larger mammals that sustain similar injuries. Immediate treatment involves establishment of a patent airway and administration of oxygen via mask, endotracheal tube, or nasal catheterization. In cases of severe upper airway obstruction, emergency tracheostomy may be indicated.[711c] Aggressive intravenous crystalloid therapy is indicated to establish and maintain a normal systemic blood pressure and to ensure that the brain receives adequate blood supply, with use of colloids or blood products as necessary. Principles of fluid therapy and treatment of shock are described in Chapter 34.

1004

1005

Administration of dexamethasone, methylprednisolone, mannitol, or dimethyl sulfoxide (DMSO) has been recommended for controlling CNS pressure caused by edema. The clinician should bear in mind that little or no scientific data exist to support the use of corticosteroids or DMSO in the treatment of CNS trauma, and that these drugs may have deleterious effects that outweigh any potential benefits. Doses listed below are largely anecdotal and are included because of the continued widespread tendency to use these agents, despite lack of evidence that they are effective. Studies of the use of corticosteroids in people with head injuries are ongoing, and the pendulum of opinion continues to swing between positive and negative.[711d] An empiric recommendation for the treatment of horses is administration of dexamethasone at 0.1 to 0.25 mg/kg by slow IV injection every 4 hours for 1 to 4 days or, for mature animals, 100 to 1000 mg of methylprednisolone by slow IV injection.[716] Similar dosages could be used in ruminants.

Data supporting the use of methylprednisolone sodium succinate for treatment of acute spinal cord injuries in people comes from the National Acute Spinal Cord Injury Study (NASCIS). A dose of 30mg/kg bodyweight given by intravenous infusion within 8 hours of injury has been recommended, followed by a second and third dose (15 mg/kg each) given intravenously 2 and 6 hours later and a subsequent infusion of 2.5 mg/kg/hr for the next 48 hours.[717] The use of a similar treatment for head injuries does not yet have good scientific support. In addition, the methodology and results of the NASCIS study have been called into question. The potential deleterious effects of such high doses of corticosteroids in large animal species include enhanced

susceptibility to infection, muscular weakness, renal potassium and calcium loss, abortion in ruminants, and laminitis in horses. These adverse consequences of corticosteroid use probably outweigh its uncertain benefits. Table 35-8 presents a list of antiedema drugs often administered to large animals with traumatic brain disease.

Table 35-8 Recommended Drug Dosages for Treatment of Cerebrocortical Edema

Drug	Dose	Route	Frequency
Methylprednisolone	30 mg/kg	IV	Once
	15 mg/kg	IV	2 and 6 hours after 30-mg/kg dose
	2.5 mg/kg/hr	IV	Constant infusion, begin 6 hours after 30-mg/kg dose
Dexamethasone	1–4 mg/kg	IV or IM	Twice daily
Mannitol	0.25–2 g/kg	IV (20% solution)	Twice daily; monitor plasma osmolality; keep below 350 mOsm/L
Furosemide	1 mg/kg	IV, IM, or SC	Twice daily; monitor plasma, calcium, and potassium
Flunixin meglumine*	1 mg/kg	IV, IM, or SC	Twice daily
Phenylbutazone* (horse)	2–4 mg/kg	IV	Twice daily
Phenylbutazone† (cow)	10–20 mg/kg	PO	Initial dose
	2.5–5 mg/kg	IV	Alternate days
Dimethyl sulfoxide (DMSO)‡	0.5–2.5 g/kg	IV (20% solution)	Twice daily
Acetylsalicylic acid	31.2–62.4 g/500 kg	PO	Twice daily

IM, Intramuscular; *IV,* intravenous; *PO,* oral; *SC,* subcutaneous.

* Monitor patient for gastrointestinal bleeding.

† Half-life of phenylbutazone in plasma of the cow is prolonged. Continuous use of the drug in cattle should be accompanied by careful monitoring of renal function and gastrointestinal bleeding.

† Doses of DMSO ranging from 0.5 to 1 g/kg are most often used. Use only in a well-ventilated area. If intravascular hemolysis develops, dilute DMSO to 5% final concentration. DMSO may be toxic for pregnant humans, and therapeutic efficacy may be limited.

The use of the osmotic diuretic mannitol has regained favor in the treatment of head trauma in humans.[711d] Intravenous administration of a 20% solution of mannitol (1 g/kg) or oral administration of glycerol (20 mL/kg) has been used for the treatment of increased ICP in large animal species. The physiologic activity of mannitol for lowering the CSF pressure may be related more to its vasoconstrictive effects than its activity as

an osmotic diuretic. Response to the treatment may occur as early as 1 hour after administration. Mannitol is expensive and usually only economically justifiable for use in neonates. If response to the initial mannitol dosage is noted, additional treatments should be given every 4 to 6 hours for the first day. Mannitol should be administered through blood administration filter sets to minimize the occurrence of microcrystalline emboli. The drug should not be given to animals with active CNS hemorrhage, because diffusion of mannitol into the center of a newly forming hematoma exerts an osmotic effect, enlarges the size of the lesion, and further attenuates the nervous system tissues. Active CNS hemorrhage can be recognized by the presence of unclotted blood in the nose or ears, or parietal bone fractures that lacerate the dorsal sagittal sinus. Despite this provision, administration of mannitol is probably justified in an animal with rapidly worsening and potentially fatal deterioration in neurologic status, even in the likely presence of intracranial hemorrhage.

Intravenous use of DMSO has been recommended for the reduction of increased CSF pressure in large animals. The drug is administered IV at 0.5 to 4 g/kg twice daily.[701,712,718,719] DMSO is diluted fivefold to tenfold in saline (10% to 20% solution) to minimize the hemolytic and hyperthermic effects. In horses, administration of 5L of 10% DMSO in a balanced electrolyte solution has been shown to have minimal deleterious clinical or clinicopathologic effects.[719a] Higher doses (solutions >20%) have been reported to have a number of adverse side effects such as intravascular hemolysis, colic, diarrhea, muscle tremors, and collapse.[719b] The use of DMSO for cerebral trauma is controversial, and benefits may be species specific. For example, anecdotal reports of benefit have been shown for horses, but controlled experiments in dogs have shown limited clinical benefit when treating experimental CNS trauma.[714]

1005

1006

DMSO has several beneficial pharmacologic actions, including free-radical scavenging, interference with neutrophil chemotaxis, prevention of microthrombi, increased penetration of corticosteroids and antibiotics into the brain, and vasodilation.[720] A major effect of the drug is probably caused by its diuretic action, which is greater than that of furosemide. In experimental situations, administration of DMSO to animals with experimentally induced CNS lesions resulted in more rapid neurologic recovery than treatment with urea, corticosteroids, or mannitol.[720] The adverse effects of DMSO include muscular fasciculations, intravascular hemolysis, hemoglobinuria, and sweating.[719] Deaths have been reported in laboratory animals after intraperitoneal injections of 10 mg/kg and in dogs after IV dosages of 2.5 mg/kg.[721–723] The median lethal dosage of DMSO in large animals is unknown. The drug is teratogenic when administered to pregnant laboratory animals.[722,723] When the drug is administered IV, approximately 70% of the dosage is excreted through the respiratory tract.[724] These data indicate that DMSO should be administered only in well-ventilated areas. Exposure of pregnant women and animals should be avoided. In cattle, DMSO is excreted rapidly and is essentially completely cleared from the plasma by 5 days.[724] A low-level residue of DMSO may persist in the fat tissues for at least 20 days. When administered IV to horses at 1.0 and 0.1 g/kg, the biologic half-life of DMSO is 8.6 and 9.8 hours, respectively.[719]

Depression fractures of the frontal and parietal bones may be reduced surgically. Lacerations of cerebral tissue can be treated surgically with gentle cleaning and debridement of contaminated and devitalized tissue.[725] Such procedures require general anesthesia. Prognosis in animals with exposed and contaminated brain tissue is very guarded, so expectations should be realistic before such intervention is undertaken. Surgical repair of skull fractures in horses using intrafragmentary wires or bone plates may be indicated to improve functional and cosmetic outcomes.[725a,725b]

Convulsions may be controlled initially by IV administration of diazepam (Valium), phenobarbital, or pentobarbital. The recommended dosages and mode of administration of these drugs are presented in Table

35-7. Good nursing care is essential. These drugs are usually highly protein bound in plasma and can be displaced or functionally altered by other drugs. All anticonvulsant treatments should begin at the lowest possible dosage, which can be increased daily or every second or third day until the seizures have been controlled. If seizures cannot be controlled without causing depression or ataxia, a second anticonvulsant is added. The dosage of the second drug is increased gradually until the seizures stop. This combination treatment is continued for 2 to 4 weeks. Thereafter, the dosage of the first anticonvulsant is tapered until it is discontinued. If seizures reappear, the dosage of this drug is increased until the seizures disappear again. The trough blood concentration of all anticonvulsants is checked monthly. The suggested therapeutic trough concentration of phenobarbital ranges from 15 to 40 µg/mL of plasma and that of diphenylhydantoin from 5 to 20 µg/mL. Any attempt to withdraw anticonvulsant therapy should be done gradually over a 4-week period.

Horses with recurrent convulsions should not be ridden or used for sporting purposes. Infrequent seizures generally do not justify anticonvulsant treatment, and economic considerations often limit the amount of drug therapy that is possible. Status epilepticus can be treated with IV diazepam in 5-mg doses until seizures are controlled or by titrated doses of phenobarbital or pentobarbital. Mares with estral-related seizures may be treated with an ovariectomy.

35.2.24 TRAUMATIC OPTIC NERVE BLINDNESS OF HORSES

Severe blunt trauma to the skull of young horses may result in a rapid caudal displacement of the brain and avulsion or stretching of the peripheral optic nerve. The condition often follows basisphenoid fractures or nonfracturing blows to the poll region (see preceding section). The clinical signs include blindness, loss of pupillary reflexes, and pupillary dilation. Ophthalmoscopic changes in the retina include pallor of the optic discs, reduction in the number and caliber of the retinal vessels, and linear peripapillary pigment disruptions. The condition is permanent.[726]

35.2.25 NERVOUS COCCIDIOSIS

35.2.25.1 Definition and Etiology

Nervous coccidiosis is a neurologic syndrome of calves and yearling cattle, sheep, and goats that is associated with enteric infections by *Eimeria* species. The condition is most often seen in western Canada and the northwestern United States and is especially prevalent in feedlots. The incidence of nervous coccidiosis is highest in the winter months. In contrast to enteric coccidiosis, mortality from nervous coccidiosis can be as high as 72%.[727] The pathogenesis of the encephalopathy may be related to the elaboration of a labile neurotoxin by the parasite.[728] The clinical signs and history of nervous coccidiosis are similar to those of other neurologic diseases that affect the function of the cerebral cortex.

35.2.25.2 Clinical Signs

The onset of the nervous system signs is usually preceded by diarrhea, tenesmus, and hematochezia. Some calves with severe diarrhea develop prolapsed rectums. Initial signs of CNS dysfunction include depression, incoordination, twitching, and hyperesthesia. As the clinical signs worsen, the animal becomes recumbent and develops numerous cerebrocortical signs, including opisthotonos, periodic tremors, horizontal nystagmus, frothing at the mouth, bellowing, snapping eyelids, and muscular fasciculations.[729–732] Blindness

is rarely seen. Stimulation of the patient may precipitate a tonic-clonic seizure.[729–732] The animal may die after 1 to 5 days of encephalopathy. Convulsive calves may regain consciousness but relapse a week later.[733]

35.2.25.3 Clinical Pathology

Fecal flotations from the patient and herdmates show a large burden of coccidial oocysts. Fecal egg counts of affected animals may range from 5000 to 4 million/g. To exclude the possibility of other neurologic diseases, blood should be collected for measurement of electrolytes (calcium, magnesium, potassium). The acid-base status, plasma glucose, and blood lead concentrations should be measured. Acute meningitis and salt poisoning may be ruled out by CSF analysis. The plasma vitamin A concentration should be measured in any animal that has not had exposure to green forage. Polioencephalomalacia, ethylene glycol poisoning, lead poisoning, rabies, petroleum distillate poisoning, and clostridial enterotoxemia should be considered as possible differential diagnoses.

35.2.25.4 Pathophysiology

The pathogenesis of the encephalopathy is unknown. The nervous form of coccidiosis cannot be transmitted to mice by injection of CSF from infected calves; however, a heat-labile neurotoxin has been identified in the serum of calves with nervous coccidiosis.[728] The encephalotoxic activity is precipitable with 30% ammonium sulfate and may have an apparent molecular weight of 300,000 kD.[734] The coccidia do not directly invade the CNS.

1006 1007

35.2.25.5 Epidemiology

Nervous coccidiosis occurs most frequently in feeder cattle, but dairy and pastured beef calves, lambs, and kids also may be affected occasionally. In one epidemiologic survey the prevalence of nervous coccidiosis was 0.3% of the calves that were affected with the intestinal form of the disease. Nevertheless, outbreaks with a large percentage of calves developing CNS disease have been reported.[729] In western Canada, nervous system signs have been reported in 21% of herd outbreaks of intestinal coccidiosis.[735] Approximately 90% of all cases of nervous coccidiosis occur in January, February, and March.

35.2.25.6 Necropsy Findings

No macroscopic lesions are seen in the CNS of calves with nervous coccidiosis. The microscopic lesions of the brain are mild and nonspecific and include edema, congestion, and occasional shrunken neurons. Parasitic invasion of the ileum, cecum, and colon results in lesions in these organs.

35.2.25.7 Treatment and Prevention

Treatment should include 2 to 4 mL/kg of a commercially available calcium gluconate solution that contains magnesium, given subcutaneously. The coccidial infection should be treated with sulfamethazine (110 mg/kg PO for 5 days, or 1 pound/100 gallons of drinking water), or amprolium (50 mg/kg/day PO for 7 days). Diazepam, sodium pentobarbital, or phenobarbital may be used to control tonic-clonic convulsions (see Table 35-3). Slow IV administration of 50 to 100 mL of a 10% magnesium sulfate solution may also be useful as a sedative. The response to treatment is poor and the case-fatality rate is high (~90%) in calves that

develop tonic-clonic seizures. Specific chemotherapeutic regimens and methods of preventing intestinal coccidiosis are described in Chapter 49.

35.2.26 SPOROZOAN INFECTIONS OF RUMINANTS (*SARCOCYSTIS* INFECTION)

35.2.26.1 Definition and Etiology

The three recognized species of *Sarcocystis* that infect cattle—*S. cruzi, S. hominis,* and *S. hirsuta*—are sporozoan parasites with definitive hosts of dogs, primates, and cats, respectively.[736,737] Three other *Sarcocystis* species—*S. capricanus, S. ovicanus,* and *S. tenella*—have definitive hosts in dogs and secondary hosts in goats and sheep.[738]

When a carnivore ingests flesh from an infected cow, *Sarcocystis* cysts in muscle are broken down by digestive enzymes, and motile bradyzoites are released. The bradyzoites infect the intestinal mucosal cell and differentiate into sexual stages called microgametes (male) and macrogamonts (female). The gametes fuse to form an oocyst, which is shed onto pastures as sporocysts. When eaten by a ruminant, the sporocysts hatch in the proximal small bowel and penetrate into the medium-sized mesenteric arteries, where they enter endothelial cells and form sporozoites. The sporozoites then mature in three successive waves. Each wave of development spreads downstream. The third-generation merozoites finally enter the soft tissues and encyst as sarcocysts. The total period of development in the ruminant requires 10 weeks. The life cycle is completed whenever a carnivore ingests uncooked meat containing viable sarcocysts. Chronic illness in the cow occurs during the maturation of the cyst in the muscles, at approximately 9 weeks after infection.

35.2.26.2 Clinical Signs

Most cases of *Sarcocystis* infestation are asymptomatic in both definitive and secondary hosts. However, if a large number of sporocysts are ingested by a nonimmune ruminant, clinical illness may develop. Clinical signs in cattle usually begin between 9 and 11 weeks after ingestion of infectious sporocysts. These signs include fever (>39.5°C [103.5°F]), anorexia, weight loss, symmetric lameness, and diarrhea. Neurologic signs include ataxia, muscular weakness, tremors, hyperexcitability, hypersalivation, recumbency, tonic-clonic seizures, leg biting, blindness, opisthotonos, and nystagmus.[739,740] Cattle may lose the hair of the tail switch (“rat tail”). Sheep may show a wool break.[736–749] Animals with chronic infections may develop edema of the limbs, poor weight gain, muscular atrophy, and pallor.[736–752] Second-trimester abortions may occur in cattle and small ruminants beginning 28 days after ingestion of infectious sporocysts.[743] The fetuses may appear either normal or autolyzed. Lactating cows may have reduced milk production.[752]

35.2.26.3 Clinical Pathology and Pathogenesis

Prolonged prothrombin times may be observed in some infected animals[736]; however, the activated clotting times and bleeding times are normal. The concentrations of plasma lactate dehydrogenase, alanine transaminase, sorbitol dehydrogenase, and blood urea nitrogen are increased. The packed cell volume (PCV) and the serum protein concentration are decreased. During early infection there is a marked normocytic, normochromic anemia that is characterized by 75% reduction of the blood hemoglobin concentration and reduced PCV.[753–755] The anemia is thought to be caused by extravascular hemolysis.[756]

Antibodies to solubilized freeze-dried *Sarcocystis* antigens have been detected by indirect hemagglutination, enzyme-linked immunosorbent assay (ELISA), and an agar gel immunodiffusion (AGID) test.[757–759] Immunoglobulin M (IgM) responses first occur by 3 to 4 weeks after infection and peak by 11 to 15 weeks.[757–759] The concentrations of *Sarcocystis*-specific IgG begin to rise by 5 to 6 weeks and peak after 11 weeks postinfection, with peak seroreactivity occurring by 39 days after infection. Background titers of normal cattle range from 1:54 to 1:486, and titers of infected cattle often exceed 1:10,000. There is no serologic cross-reactivity between *Sarcocystis* and *Toxoplasma gondii,* despite their physical similarities.[751]

35.2.26.4

Pathophysiology

The pathogenesis of *Sarcocystis* is poorly understood. Pathologic changes in the skin and muscle and in serum chemistry probably are related to a combination of parasite-directed immunologic responses and diffuse vasculitis. Although toxins have not been identified, rabbits die acutely after parenteral administration of purified bradyzoites. The clinical signs exhibited by the inoculated rabbits resemble endotoxic shock. Other studies have indicated that chronic infections result in increased concentrations of somatostatin and decreased concentrations of somatomedin.[760] Abortions probably occur because of luteolysis that results from the increased concentrations of prostaglandin $F_{2\alpha}$, caused by vascular infection by the parasite.[761]

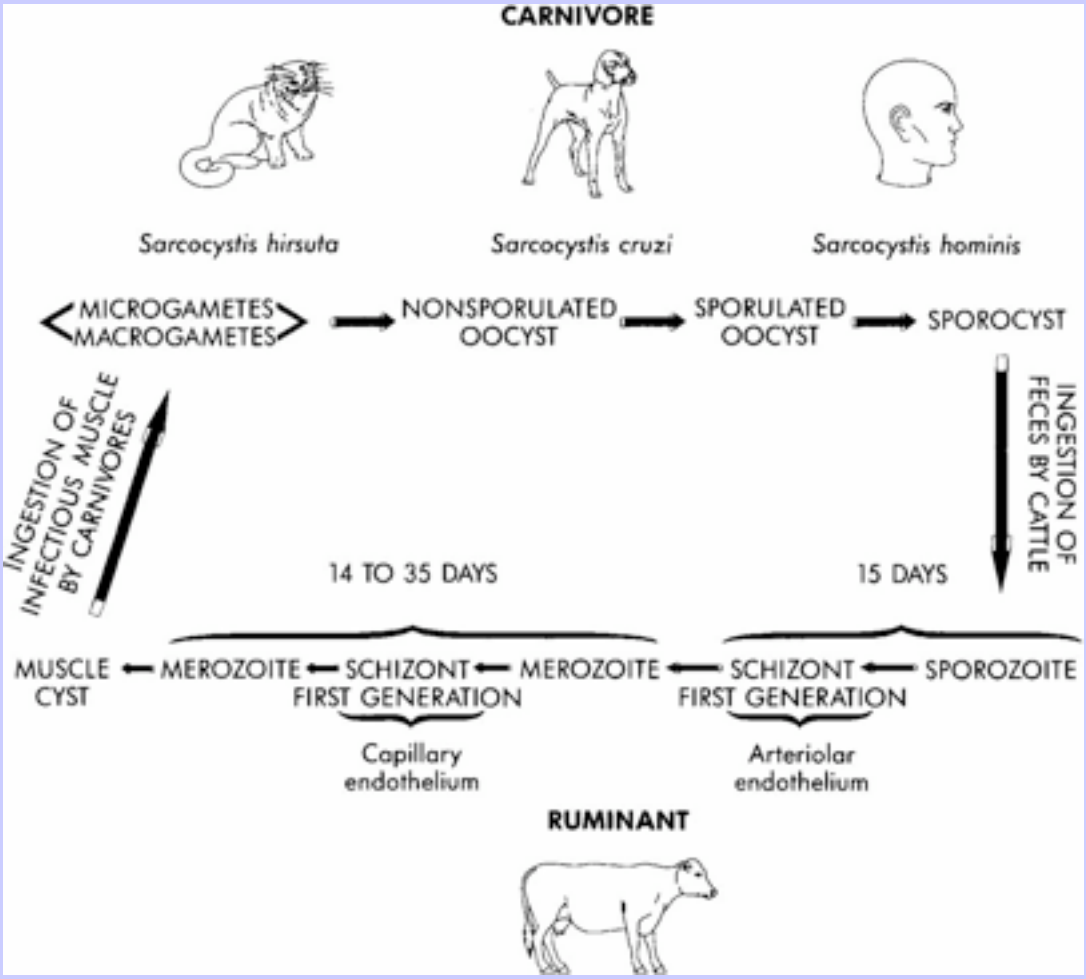
35.2.26.5

Epidemiology

Estimates of infection rates range from 70% to 98% in cattle in the United States.[736] When infected flesh is eaten by carnivores, the encysted sporozoites complete their life cycle[736] (Fig. 35-7). The prepatent period of the parasite in the carnivore (primary host) ranges from 9 to 45 days. The primary host may shed the sporulated oocysts in the stool for as long as 2 months after a single infection. The oocysts withstand freezing but are rapidly killed by sunlight and drying.[736] Reexposure of previously infected canids results in a large fecal output of sporocysts. Ingestion of approximately 250 g of infected meat by a dog can result in an output of 100 to 6000 sporocysts per gram of feces. Wild canids are even more susceptible than domestic dogs and may serve as a major mechanism for propagation of *Sarcocystis* in range cattle in the western United States.

1007
1008

Fig. 35-7 Life cycle of *Sarcocystis* parasite.



Most *Sarcocystis* infestations of cattle are asymptomatic; however, the disease may become clinically apparent with sudden, overwhelming exposure to the parasite in a nonimmune animal. Such conditions occur whenever there is an opportunity for extensive scavenging of ruminant carcasses by carnivores and contamination of feed bunks or pastures with infected carnivore feces.

The economic burden of *Sarcocystis* infection is unknown. One author has estimated an annual loss of $95 million in the United States alone.[736]

35.2.26.6

Pathologic Lesions

The pathologic lesions of the CNS are similar for all species of sporozoans; they include granulomatous meningoencephalomyelitis, focal malacia, perivascular cuffing, neuronal degeneration, and gliosis. The changes are generally most severe in the cerebellum and midbrain but can occur anywhere in the CNS,

including the spinal cord. The pathologic diagnosis is based on finding meronts and merozoites in the affected sections of neural tissue.[762,763]

Pathologic lesions elsewhere include hemorrhages on the sclera, serous surfaces, and muscles; fluid in the body cavities; and lymphadenopathy. The muscles have alternating light and dark stripes. Macroscopic changes may not be evident in animals with chronic sarcocystosis.[741,742] If changes are not evident, postmortem diagnosis is based on the finding of intravascular schizonts or intramuscular hemorrhages without significant inflammation. Ultrastructural examination of affected areas of CNS shows an intracellular colony with rosette orientation of agents in the cytoplasm of infected astrocytes.

35.2.26.7 Treatment

Feeding monensin (100 mg/kg daily for 30 days) during the incubation period is prophylactic; however, the efficacy of the drug in symptomatic cattle is unknown. For maximum effectiveness, monensin should be administered continuously for 2 to 5 weeks after exposure. Treatment of infected sheep with salinomycin (1 to 2 mg/kg) also has been recommended.[764] Administration of amprolium (100 mg/kg once daily for 30 days) may reduce the severity of *Sarcocystis* infection[765] but may not completely eliminate the clinical disease.

35.2.26.8 Control

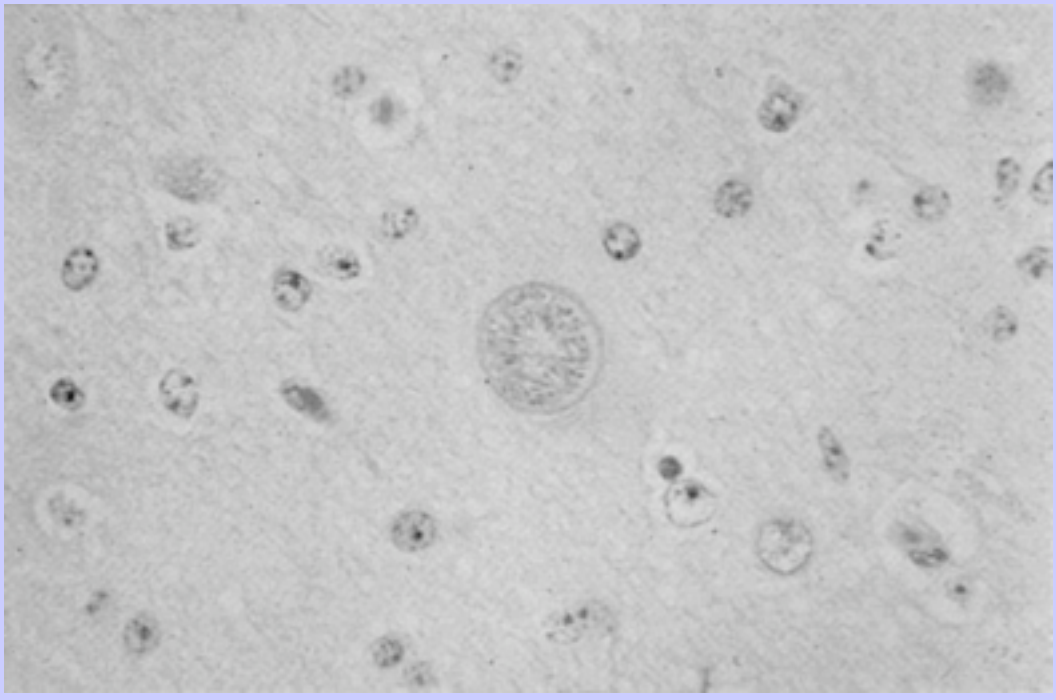
The best method of controlling *Sarcocystis* infection is to protect the food supply of ruminants. Scavenging of carcasses by carnivores should also be prevented by deep burial or incineration. Feed bunks should be kept clean and raised approximately 1 to 3 feet (30 to 90 cm) off the ground. All carnivorous pets that have access to the feed or pastures should be fed cooked meat or processed dry food. In range pasture situations, prophylactic feeding of monensin or elimination of predatory or scavenging carnivores may be necessary.

35.2.27 NEOSPORA INFECTION OF CATTLE (PROTOZOAL ABORTION)

35.2.27.1 Definition and Etiology

A cyst-forming protozoal parasite that closely resembles *Neospora caninum* has been identified in aborted fetuses from cattle in California. The condition is predominantly a disease of dairy cattle; however, sporadic abortions can occur in beef cows.[766–768] The predominant clinical sign of a *Neospora*-like agent is a midterm to late-term abortion (3 to 8 months of gestation). Fetal lesions consist of a focal nonsuppurative necrotizing encephalitis, nonsuppurative myocarditis and myositis, and mononuclear cell infiltrates disseminated in other tissues. Occasionally, calves are mummified. The agent appears to have been responsible for as many as 24% of all abortions in northern California dairy cattle.

Fig. 35-8 Calf with congenital *Neospora* infection of the central nervous system *(left)* and a tissue cyst containing *Neospora* tachyzoites *(right)*.



Occasionally, however, a nonfatal infection may occur in the fetus. In this case the fetus is born with neurologic dysfunction (Fig. 35-8). The clinical signs of neurologic disease vary because of the randomly widespread distribution of the parasite within the CNS. Affected calves are often unable to stand and suckle and have abnormal spinal reflexes. Flexural contractions of the forelimbs, domed skull, and torticollis have also been reported in spontaneously occurring cases.[769,770] The calves are usually born with the CNS signs, which initially are mild but then progress after birth. Pathologic lesions associated with the fetal infection include focal areas of brain discoloration, focal cavitation with cyst formation, and reduction of gray matter. Microscopic changes in the CNS of affected calves include nonsuppurative inflammation of the gray and white matter, demyelination, perivascular cuffing, focal lymphocytic meningitis, and neuronal necrosis. Changes in other tissues include nonsuppurative myocarditis, myositis, and hepatitis. Protozoa can be seen in microscopic sections of the stained tissues.

Neospora organisms have been isolated in pure form using cultured cells.[771] Antibodies have been produced by intubation of laboratory animals, and the agent can be identified microscopically using immunoperoxidase staining on the fixed tissues. The CSF changes in affected calves range from normal to mild pleocytosis.[772] Similar conditions have been described in sheep[773,774] and goats.[775,776]

35.2.28 EQUINE PROTOZOAL MYELOENCEPHALITIS (*TOXOPLASMA*-LIKE AGENT; PROTOZOAL ENCEPHALOMYELITIS; SEGMENTED MYELITIS)

35.2.28.1 Definition and Etiology

Equine protozoal myeloencephalitis (EPM) is a multifocal, progressive disease of the central nervous system (CNS) that is primarily caused by infection with *Sarcocystis neurona*.[777] Recently, another protozoan parasite, *Neospora caninum/N. hughesi,* has been implicated as a cause of EPM in six cases.[778–783] The condition has mostly been reported from many U.S. states, Canada, Panama, Brazil, and Argentina.[784–790] Several reports of the disease in countries other than those in the Western Hemisphere were primarily in horses that originated from the Americas.[791–794] More recently, there have been reports of horses in France that developed neurologic deficits with positive *S. neurona* antibody titers that were native to France and had not resided in the United States.[795,796] Young standardbred, thoroughbred, and quarter horses are most often affected, although horses of any breed may develop the disease. There does not appear to be a gender predilection for EPM, and any age may be affected.[797] The risk would appear to be higher in young horses, but horses as old as 30 years have developed the condition.[797]

The parasite produces inflammation and necrosis of the brain, brainstem, and spinal cord. Under light microscopy, the structure of the EPM agent resembles that of *Toxoplasma gondii,* but comparative electron microscopic analyses of the three agents show differences. The *Sarcocystis* agent of horses has been grown in explant cultures of monolayered bovine monocytes.[787,798] Antibodies in the sera or cerebrospinal fluid (CSF) can be detected using these specimens as probes of immunoblots of the cultured parasites. Sera from clinically affected cases recognized eight *S. neurona*—specific antigens,[799] several of which are the basis for current diagnostic testing. DNA analysis has been very important in characterizing and classifying *S. neurona*. Using a random primed polymorphic DNA assay (RAPD), a unique sequence of base pairs was identified that distinguished *S. neurona* from eight related coccidia, specifically two *Sarcocystis* species, one

Toxoplasma species, and five *Eimeria* species.[800] This research demonstrated that unique DNA sequences could be successfully used as a species-specific probe for *S. neurona,* and that these probes permitted differentiation of *S. neurona* from other coccidia of equines.[800]

35.2.28.2 Clinical Signs

Descriptions of clinical signs of horses diagnosed with EPM may vary greatly because the organisms that cause this disease can affect any CNS tissue. Therefore, any horse exhibiting neurologic abnormality could be diagnosed with EPM.

Clinical signs recognized in the earliest studies of this disease still characterize neurologic abnormalities in horses with EPM. Early workers described horses with EPM as having an asymmetric ataxia and associated muscle atrophy.[801,802] Horses may have a sudden onset of clinical signs, or disease may progress slowly over several months.[801] Vague, intermittent lameness that is nonresponsive to therapy may be caused by EPM, and encephalitic signs typified by asymmetric cranial nerve deficits may also be seen in affected horses.[801] Gait abnormalities in horses with EPM include ataxia, tetraparesis, knuckling, circumduction, and crossing over. The abnormalities may be asymmetric. Depending on the location of the lesion in the spinal cord, areflexia, hyporeflexia, or hyperreflexia may be seen. Infections of the myelencephalon may result in head tilt, facial paralysis, circling, nystagmus, dysphagia, facial paralysis, and apparent blindness, with or without abnormal pupillary reflexes. Parasitic invasion of the ventral spinal rootlets or the radicles of the maxillary branch of the trigeminal nerve may result in neurogenic atrophy of the tongue and masticatory muscles (Fig. 35-9). This is often accompanied by focal areas of desensitization. Regional sweating ("strip sweating") may be observed if the sympathetic tracts of the spinal cord are affected. Although EPM is typified by the presence of asymmetric, multifocal neurologic abnormalities, horses with EPM may have focal or symmetric signs.

Fig. 35-9 Unilateral atrophy of the tongue in a standardbred horse with protozoal myeloencephalitis. Atrophy also may occur in many other muscle groups of the head and the limbs. Courtesy Dr. R.H. Whitlock.

Cerebral signs are rarely seen in horses with EPM. However, three horses with EPM presented to Ohio State University Veterinary Teaching Hospital displayed seizure activity and evidence of cortical electrical activity abnormalities on electroencephalographic (EEG) examination.[803] Horses with cerebral neurologic signs often have a poor prognosis. However, seizure activity in horses with EPM may be treatable. Visual deficits and behavioral abnormalities have been reported in horses with EPM.[804] Head shaking was also reported in a recent case series describing three horses diagnosed with EPM.[805] Head shaking resolved in these horses after treatment for EPM. Recently, urinary incontinence and incoordination have been reported in three horses diagnosed with EPM. Resolution of the clinical signs were mixed in those cases.[806]

Differential diagnoses of the most common neurologic diseases of horses that resemble EPM include equine degenerative myelopathy (EDM), cervical spinal injuries, cervical vertebral stenosis or malformation (CVM), equine herpesvirus type 1 (EHV-1), and equine lower motor neuron disease (ELMND).

Another disease has become the number-one differential for EPM over the last 7 years. West Nile Virus (WNV) was first reported in the United States in 1999; however, the number of equine cases has increased consistently from 25 in 1999 to greater than 14,000 in 2002.[807] Almost all the equine cases in 1999 had been diagnosed with EPM first before a definitive diagnosis of WNV was determined.[808] Asymmetric neurologic deficits with profound weakness and ataxia make it difficult to differentiate WNV from EPM.

35.2.28.3

Clinical Pathology

A Western blot (WB) analysis for the diagnosis of EPM has been described and commercially marketed.[799] Macrophage-cultured *S. neurona* is used as the antigen. After electrophoresis the blots are probed with suspect CSF or serum. Reactions are seen as bands developing on the blotted membrane. The sensitivity and specificity of WB has been reported as 89% based on 295 postmortem examinations.[809] However, these figures are likely based on more severe cases. Although promising, exhaustive examinations of the sensitivity and specificity of the test in clinical cases are not yet available. Recent research suggests that the sensitivity is excellent, but the specificity in current clinical cases is much lower than originally reported.[810] There is no apparent serologic cross-reactivity between the parasites of EPM (*S. neurona* and *N. caninum*) and *T. gondii*. Use of the WB for antibody to *S. neurona* differs depending on the prevalence of the disease in the population studied.[811] If the test is applied in the normal horse population, where the prevalence of EPM is likely less than 1%, the predictive value of a positive test is extremely low (<8%) based on the 89% sensitivity and specificity. However, given the presence of neurologic signs, the prevalence increases dramatically (50% at Ohio State), leading to a positive predictive value of about 90%. This suggests the test should not be applied in normal horses. A recent report demonstrates that the specificity of WB was much lower than originally reported.[812] Another report attempted to demonstrate increased specificity for WB for *S. neurona* antibody detection by blocking the reaction using *Sarcocystis cruzi* antibody.[813] However, a double-blind investigation indicated that this increased specificity is questionable (William J.A. Saville, unpublished data).

Several new diagnostic tests are still measures of reactivity to antigens. Initially, a recombinant surface antigen (SAG1) protein was discovered, and an ELISA test was developed to test horses for *S. neurona* exposure.[814] However, no mention of controlled environment or heat-treated feed in this study makes it difficult to interpret the results. Further development of an ELISA test using a recombinant baculovirus-expressed SAG1 antigen was completed by others.[815] This test was able to detect both naturally and

experimentally infected horses and other species. Another diagnostic test was developed using direct agglutination, the *S. neurona* agglutination test (SAT).[816] In mice the sensitivity of SAT was 100% and the specificity 90%.[816] In California an indirect fluorescent antibody (IFA) test was developed for detection of *S. neurona* antibody.[817] This test was compared with two currently commercially available WB tests, and the results suggested that the IFA was better than either WB test with regard to specificity.[817] Further evaluation of the IFA using both naturally and experimentally infected horses resulted in likelihood ratios that would be useful in diagnosing EPM.[818] The one concern regarding this test is that it may cross-react with horses recently infected with *Sarcocystis fayeri,* another common parasite infecting U.S. horses.[819] Further research with the IFA suggests that using this test on CSF of horses has no benefit if used on the serum in the diagnosis of EPM.[820]

More recently, it has been reported that surface antigens (SAGs) of *S. neurona* are similar to the SAGs of *T. gondii*.[821] The SAGs of *S. neurona* were named SnSAG1 through SnSAG4.[821] Recombinant proteins were developed to the four SnSAGs to produce a set of ELISAs for detection of antibodies to the SnSAGs.[822] Testing these ELISAs with confirmed cases of EPM serum and CSF samples suggested that the SnSAG2, SnSAG3, and SnSAG4 assays would be good tests in the diagnosis of EPM.[822] The ELISA to the rSnSAG1 demonstrated poor sensitivity (68.2%) and specificity (71.4%), likely because of the differences in strains of the parasite, some of which do not express antibody to SAG1.[822] There was also no cross-reactivity when testing horses infected with *S. fayeri* or *Neospora hughesi*.[822] The most recent test developed for diagnosis of EPM has been the *S. neurona*—specific IgM-capture ELISA.[823] This test was developed using samples from previous experimental infection studies performed at Ohio State University.[823] The IgM titers developed and peaked between weeks 2 and 3 postinoculation (PI), and the IgM response waned by 7 weeks PI.[823] The IgM test is still a measure of exposure; however, it indicates an acute infection and therefore may be useful in the early diagnosis of EPM.[823] Further evaluation of this diagnostic test is needed using large numbers of field tests.

Regardless of the tests developed in the past few years, they are primarily still tests of exposure, so diagnosis of EPM is problematic.[824] Therefore, antibodies in serum or CSF must be accompanied by asymmetric neurologic deficits followed by rule-outs of other possible causes of the neurologic deficits.[824]

One of the difficulties in diagnosing EPM is caused by the large number of horses that have detectable quantities of antibody to *S. neurona* in the CSF for several months after therapy, or in horses that do not exhibit neurologic signs. *S. neurona*—specific IgG found in the CSF is assumed to be produced locally because the blood-brain-barrier (BBB) should prevent large molecules from freely entering the cerebrospinal space. However, antibody detected in the CSF could have been produced systemically if the BBB is compromised by disease or if peripheral blood contaminates the spinal fluid during sampling. To help determine whether IgG in CSF was produced locally or resulted from peripheral blood contamination, a series of tests were modified from those used in human patients with neurologic diseases. The albumin quotient (AQ) and the IgG index are calculated using concentrations of albumin and IgG found in serum and CSF of the patient.[825] The AQ is a measure of BBB integrity, and the IgG index is a measure of intrathecal antibody production.[825] Some reports suggest that horses with EPM usually have a normal CSF albumin concentration and a normal AQ, but the IgG index is usually elevated.[826] It has been suggested that these indices, specifically an elevated AQ, can be used to distinguish true-positive WB tests in horses with EPM from false-positive tests resulting from blood contamination during sampling.[826] False-positive results

caused by blood contamination may alter the AQ and the IgG index by increasing the albumin and IgG concentrations in the CSF.[826] It has also been recommended that the CSF indices may be used to monitor the response to therapy for EPM by identifying a decrease in the IgG index that would mark a decrease in intrathecal antibody production over time. However, small numbers of horses were used in the initial evaluation of these tests, with some inconsistencies in the reported results. Although the IgG index did decrease in 9 of 12 (75%) horses treated for EPM, 3 of 12 horses demonstrated an increase in the IgG index.[827] The reliability of the CSF indices has been questioned by others.[828,829] One controlled investigation suggests the CSF indices are inconsistent, therefore, if used, they should be interpreted with caution.[810]

Polymerase chain reaction (PCR) is available to aid in diagnosing EPM.[830,831] The sensitivity and specificity of PCR testing of CSF has been reported to be 83% and 100%, respectively, when histologically confirmed cases of EPM were used to validate the assay.[832] However, other research suggests that the sensitivity of PCR may be only about 40%.[833] PCR requires that parasite DNA be intact. A strong inflammatory response favors enzymatic degradation of parasite DNA, and this process may affect sensitivity of the PCR test. Therefore, PCR may be useful early in the course of the disease and in chronic cases.[832] In addition, PCR analysis of CSF may be insensitive because the parasite is most frequently found in tissues and not floating freely in the CSF. Therefore, parasite DNA may not be present in CSF, even when adjacent tissue is infected.[833] *Toxoplasma gondii* infections are difficult to detect in people for the same reasons.[834] A recent study of clinical cases found that PCR alone was not useful for antemortem diagnosis of EPM based on the low sensitivity (12/151).[829]

Sarcocystis neurona DNA has been detected in blood samples. The presence of DNA in blood samples is thought to indicate recent ingestion of *S. neurona* sporocysts and subsequent infection. However, it is not known how long detectable amounts of DNA remain in the blood stream after infection.[832] Controlled investigations of PCR testing in horses with neurologic deficits as well as in normal horses are required to define the usefulness of this procedure.

Cerebrospinal fluid analysis has been used to aid in determining the etiology of neurologic diseases in the horse. Early studies suggested that horses with EPM had mildly elevated CSF protein concentrations, increases in numbers of mononuclear cells, and mild elevations in CSF enzyme activity (creatine kinase, CK; aspartate transaminase, AST).[835] Two early studies reported marked elevations in the CSF CK activity in horses diagnosed with EPM.[836,837] However, more recent studies suggest that neurologic disease of horses cannot be reliably differentiated based on CSF leukocyte counts, CK activity, AST activity, or protein concentration.[810,838,839]

Several serologic tests have been developed for detection of *Neospora caninum* antibodies in animal species.[840] The three methods currently used are ELISA, IFA test, and direct agglutination test.[840] However, these antibody tests are only measures of exposure to the organism. New diagnostic tests for *N. hughesi* used in experimentally infected equines included a whole-parasite ELISA, a recombinant-protein ELISA, a modified direct agglutination test, and an IFA test, which showed the most consistent results.[841] However, a recombinant NhSAG1 ELISA has been developed that suggests, with a sensitivity of 94.4% and a specificity of 95%, it may be an excellent diagnostic test for *N. hughesi* infections in horses.[842]

35.2.28.4

Pathogenesis and Pathologic Changes

Little is known about the pathogenesis of EPM. It is assumed that the horses ingest *S. neurona* and that the course of infection and disease is then similar to that observed in other host species infected with *Sarcocystis* species. Because the sporocysts of *S. neurona* are passed in the feces of the opossum, infective oocysts likely are introduced into the feed and water supply of intermediate hosts. Once ingested, the sporocysts excyst and release sporozoites, which penetrate the gut and enter arterial endothelial cells of various organs. Meronts develop and rupture the host cell, releasing merozoites into the bloodstream. This is probably followed by a second round of merogony throughout the body. In most *sarcocystis*-like diseases, this process results in the formation of sarcocysts in the muscle. Subsequent ingestion of the infected muscle tissue by the predator or definitive host completes the life cycle. Sarcocysts of *S.neurona* had not been found in affected horses, indicating that the horse is likely an aberrant, dead-end host.[843] However, a recent report suggested that the horse may develop *S. neurona* sarcocysts and therefore may be a natural intermediate host.[844] The fact that 1011
this has been seen only once in the literature is troublesome, and the inability to fulfill Koch's postulates is 1012
also a problem. Horse muscle fed to naive opossums has failed to produce sporocysts after numerous attempts (William J.A. Saville; unpublished data).

Little is known about the life cycle of *N. caninum* or *N. hughesi* in horses. Recent reports have demonstrated that the definitive host of *N. caninum* is likely the dog.[845] At present it is not known if the dog is the definitive host of *N. hughesi*. The dog is the definitive host and also can be an intermediate host, which is similar to *T. gondii* in cats.[840] Unlike EPM caused by *S. neurona,* tachyzoites have been found in horse tissues, as well as tissue cysts in two horses reported to have EPM caused by *Neospora*.[840] In addition, one case of neosporosis in a foal was determined to have been congenitally infected.[780] Congenital infections have not been demonstrated in horses infected with *S. neurona*.

Sarcocystis neurona has been recovered from CNS lesions in several horses and subsequently propagated in culture in the laboratory.[846] When administered to horses parenterally or introduced through the epidural space, cultured merozoites have not induced clinical disease in the horse.[846] The merozoite stage of *Sarcocystis* species is not known to be transmissible to other animals.[846] However, nude mice have been inoculated intraperitoneally with cultured merozoites and subsequently developed evidence of *S. neurona*—associated encephalitis.[847] These mice were immunosuppressed strains, and intraperitoneal injection would not likely be the normal route of infection with *S. neurona* in horses. A better mouse model has recently been developed by feeding sporocysts from feral opossums to interferon-γ knockout (IFN-γ/KO) mice.[848] These procedures in IFN-γ/KO mice also help to differentiate *Sarcocystis* species that are excreted in opossum feces; at least three species appear to be present.[848] The mechanism by which the merozoites enter the CNS is currently unknown. The organism likely enters the CNS through infected leukocytes or through the cytoplasm of endothelial cells.[846] Recent research may help in confirmation of this speculation. When co-cultured with equine peripheral leukocytes, *S. neurona* merozoites penetrated the cells within 5 minutes after starting the culture.[849] This may be the mechanism for entering the CNS. In addition, a microneme protein for host cell invasion has been documented.[850]

There have long been anecdotal reports that the parasite may create immune suppression in the horse. One report demonstrated a strong association between health events and development of clinical signs of EPM.[797] Earlier reports suggested that nitric oxide is important to resistance to intracellular parasites, decreased nitric

oxide was reported in horses with experimental and naturally occurring cases of EPM.[851] Another report indicated that decreased levels of transforming growth factor beta (TGF-β) in CSF of horses may be important in development of EPM.[852] Two recent reports found a decrease in IFN-γ production in lymphocytes from EPM-positive horses compared with negative horses.[853,854] Other studies have corroborated these findings.[855] Two reports in mice suggest that protection against *S. neurona* infections requires CD4 and primarily CD8 cells.[856,857] This phenomenon has been demonstrated in *T. gondii* infections as well.[856,857]

Much more research is needed to elucidate the mechanisms and pathogenesis of *S. neurona* infections in horses.

35.2.28.5

Life Cycle of Sarcocystis neurona

Most specific details regarding the life cycle of *S. neurona* are currently unknown, although recent research has demonstrated that the opossum is likely the definitive host. The geographic distribution of opossums is similar to the geographic distribution of EPM, and areas with lower seroprevalence of *S. neurona* appear to coincide with regions outside the natural range of opossums.[858] Further evidence that the opossum is the definitive host for *S. neurona* was obtained by experimental induction of EPM.[859] When sporocysts from feral opossums were fed to horses, neurologic disease developed.[859] This study has been repeated by other research groups.[860–865] However, induction of clinical EPM by feeding *Sarcocystis falcatula* sporocysts was not successful.[866] More recent work has demonstrated at least three species of *Sarcocystis* sporocysts in feces from the opossum.[867] Other studies suggest that four species of *Sarcocystis* sporocysts may be present in opossum feces.[868,869] Development of DNA probes that distinguish *Sarcocystis* species will better enable researchers to characterize sporocysts from opossum feces, using additional induction studies to help develop a reliable equine model for EPM.

Several recent studies have induced experimental infection in horses with *S. neurona* sporocysts. Initially, in a University of Kentucky study, naive foals were infected with 1×10^6 to 4×10^7 sporocysts orally, which resulted in mild to moderate neurologic deficits. The sporocysts were collected from wild-caught opossums, cleaned, and administered by nasogastric intubation. Unfortunately, the parasite was not cultured from the CNS tissues, resulting in the inability to fulfill Koch's postulates.[859] At the University of Florida, three studies used sporocysts detected using molecular DNA probes.[869] One study administered 1×10^6 *S. neurona* sporocysts and another 5×10^5 sporocysts orally once daily for 7 consecutive days.[864,865] Both studies resulted in mild to moderate neurologic deficits, and no parasite was detected.[864,865] In another Florida study, sporocysts characterized as *S. falcatula* were administered to horses, with no development of neurologic signs and no seroconversion.[866] This study corroborated that the opossum excreted more than one *Sarcocystis* species of sporocysts.[866] Recently, a study at Ohio State University attempted to infect horses using 8×10^4 *S. neurona* sporocysts with three different treatment groups.[863] All nine horses in the infected groups developed neurologic signs; however, the most severe signs (mild to moderate) were seen in horses in the transport stress group. Unfortunately, as in the Kentucky study,[859] Koch's postulates were not fulfilled in the Ohio study.[863]

The previous studies attempted to mimic stress using dexamethasone, but the clinical signs were less severe, and the horses' clinical signs appeared to improve.[859,863,864] In addition, regardless of the dose of sporocysts administered, some horses demonstrated an improvement in their clinical signs with no treatment. These results suggest that horses are capable of clearing large numbers of these organisms. Those findings may explain the high number of CSF antibody-positive horses with no evidence of neurologic deficits. Equally troubling, after orally inoculating horses with 1×10^8 *S. neurona* sporocysts, clinical signs of neurologic deficits were readily detectable; however, no parasite was found in the CNS at 7 or 14 days postinfection (PI) (W.J.A. Saville and J.P. Dubey, unpublished observations). In the natural intermediate host, the raccoon, *S. neurona* was readily detectable in the CNS 7 days PI.[870]

Additional infection studies have been attempted in horses. A horse with severe combined immunodeficiency disease (SCID) received characterized sporocysts of *S. neurona* orally. Although a parasitemia was detected in this horse, the first detection of the parasite in an experimentally challenged horse, the horse did not develop evidence of neurologic dysfunction. This suggests that development of clinical signs of EPM requires an intact immune system, which also supports anecdotal evidence that EPM is a neuropathologic disease in horses.[860,871]

Studies at Ohio State University (OSU) have further characterized *S. neurona* infection in horses. The infectious sporocysts were produced using laboratory-raised opossums and infected raccoons and the life cycle as previously reported.[870,872] The second trial was done to determine the effect of sporocyst dose on development of clinical signs of EPM.[862] Horses in the group that received 1×10^6 sporocysts seroconverted earlier and developed more consistent clinical signs than those infected with lower doses of sporocysts. Horses were transported a second time and developed worsening clinical signs after residing at the Veterinary Teaching Hospital at OSU.[862] Therefore, another trial was carried out testing the effect of a second transport after infection with sporocysts immediately on arrival at the first study site.[861] The results demonstrated more significant clinical signs in the horses not transported a second time, refuting the hypothesis from the 2002 study. Neither the 2002 study nor the 2004 study resulted in detection of the parasite in the tissues of infected horses. Another study, in 2005, demonstrated that *S. neurona* could be detected in the blood of an experimentally infected, immunocompetent horse.[873] The horse had been infected daily for 98 days, and *S. neurona* was detected from the blood of one of six horses tested, demonstrating that the parasite could be detected in immunocompetent, experimentally challenged horses.[873] Because of the lack of parasite detection in equine infection models at most sites, researchers at OSU decided to attempt culture early in the infections rather than at the end of the infection period. Eight naive horses negative for antibody to *S. neurona* were included; six were infected with sporocysts derived from laboratory production using the opossum-raccoon cycle, and two were control animals.[874] Parasite was cultured from mesenteric lymph node, liver, and lung at 1, 2, and 7 days PI; 2, 5, and 7 days PI; and 5, 7, and 9 days PI, respectively.[874] Although no parasite was detected in CNS tissue, evidence of infection was present at 7 and 9 days PI.[874] This recent OSU study was able to fulfill Koch's postulates and shows evidence that the parasite can invade the tissues very quickly after ingestion, as demonstrated in previous studies in two different species of animals.[844,848,870] Further work needs to be done to examine an equine model for the disease.

Unlike most *Sarcocystis* species, *S. neurona* may aberrantly infect a large number of intermediate hosts. Although the full range of intermediate hosts for *S. neurona* has not yet been identified, several species of animals and birds have been reported to exhibit symptoms similar to those seen in horses with EPM. Several reports indicate that an *S. neurona*—like organism infected and caused neurologic disease in dogs, sheep,

cats, mink, raccoons, a striped skunk, a golden hawk, Pacific harbor seals, sea otters, chickens, a Grant's zebra, Canada lynx, and a Fisher.[875–888] The harbor seals and sea otter had evidence of sarcocysts in the muscle that were *S. neurona* positive.[878,879] This seems to be the first evidence for potential *S. neurona* sarcocysts to date, although the significance of this finding was not well understood. This positive reaction to anti—*S. neurona* antibody could be caused by cross-reactivity to other *Sarcocystis* species. A recent report indicates that *S. neurona* cycles normally between the opossum and various intermediate host species. Even though the opossum is the definitive host and does shed the parasite in its feces, the opossum does not develop antibodies to *S. neurona*.[889] Sarcocysts are found in the muscles of five species: infected domestic cats *(Felis domesticus),* nine-banded armadillos *(Dasypus novemcinctus),* striped skunks *(Mephitis mephitis),* raccoons *(Procyon lotor),* and sea otters *(Enhydra lutris nereis)*.[872,890–893] It was thought that the domestic cat was only a laboratory intermediate host, but studies in Missouri and Ohio suggest that the cat is a natural intermediate host as well;[895,894] this also seems to hold true for the striped skunk.

Recently, the life cycle of *S. neurona* has been completed in the laboratory.[892] Previous reports of serum prevalence of antibodies to *S. neurona* in striped skunks suggest that they are likely a natural intermediate host as well.[896] When muscle from wild-caught raccoons and road-killed armadillos was fed to laboratory-raised opossums, it resulted in shedding of sporocysts infective for ponies, horses, and IFN-γ/KO mice.[872,891] High seroprevalence of *S. neurona* antibodies in armadillos tested (100%) from three states and raccoons (57%) tested from four states supports that these two species are natural intermediate hosts.[891,897] After ingestion of the infected muscle, opossums shed sporocysts in their feces. Small numbers of sporocysts were found after feeding sea otter muscle, but the sporocysts were infective for IFN-γ/KO mice.[890] The role of the sea otter as a natural intermediate host is likely limited because it is a marine mammal. Results of these life cycle studies demonstrate that many species may be potential intermediates hosts for *S. neurona*. This wide host range is atypical for *Sarcocystis* species. This host range behavior is similar to that of *T. gondii,* which is phylogenetically close to *S. neurona*.[898,899]

Based on the number of intermediate hosts determined so far, a number of isolates of *S. neurona* are postulated to exist. Recent work found that there are differences between South American and North American isolates.[900,901] Also, evidence indicates that the U.S. group could be divided into northern and southern U.S. groups, which suggests geographic groupings. Other work has demonstrated differences in the SAG1 gene in different isolates of *S. neurona*, with 73% to 100% sequence similarity.[902] This is in contrast to the SAG1 gene of *Neospora* species, with 96% to 98% similarity.[902] These differences in the isolates was confirmed when monoclonal antibodies developed against immunodominant proteins of *S. neurona* failed to detect all isolates.[903]

Based on the estimated numbers of opossums in North America, the poor survival rate of these animals, and the small areas in which they travel, *S. neurona* may be transmitted by routes other than direct contact with opossum feces. Experiments performed by researchers in the 1980s indicate that some transmission may occur through birds.[904] In experiments attempting to characterize the life cycle of *S. falcatula,* birds were apparently infected by aerosol spread.[904] Vector transmission was also demonstrated by the recovery of sporocysts after budgerigars, canaries, white mice, and chickens were fed opossum feces.[905] The recovered sporocysts were then fed to budgerigars to assess the viability of the sporocysts. Four of six budgerigars died, demonstrating that the sporocysts were viable. These experiments suggest that sporocysts might be transmissible between intermediate hosts. Considering the apparent wide range of natural and aberrant intermediate hosts for *S. neurona* and *S. falcatula,* transmission of infectious organisms between intermediate

hosts implies that control of disease caused by these organisms may be extremely difficult. Insects such as flies and cockroaches may also be transport vectors for *S. neurona*. Early work demonstrated that flies and cockroaches may act as transport vectors for *T. gondii*.[906,907] In addition, fatal pulmonary disease developed in psittacine birds fed cockroaches after the cockroaches had been fed opossum feces.[908] Although this suggests that insects may play a role in transmission of *S. neurona*, further investigation is necessary to determine which insects are actually involved in its life cycle.

Stress may play a role in the development of EPM,[843,899] but limited evidence is available to support this hypothesis. The severity of EPM may be related to the size of the infective dose, immune competency of the host, and the environmental stresses to which the horse is exposed.[846] A similar association between immunosuppression and disease has been documented in other species with EPM-like symptoms. For example, recent mouse models have been developed for EPM using nude mice and IFN-γ/KO mice, both of which are immunocompromised strains.[847,848] Raccoons have been identified that were concurrently infected with a *Sarcocystis*-like protozoan and canine distemper virus (CDV).[884,909] Interestingly, CDV is known to 1013
be immunosuppressive and has often been associated with cerebral toxoplasmosis in dogs, foxes, and 1014
raccoons.[909] Immunocompromised people are often infected with *T. gondii,* and stress plays a major role in the recrudescence of the clinical signs of *T. gondii*—associated encephalitis.[910] Infections with either *N. caninum* or *T. gondii* can cause T-cell hyporesponsiveness to the parasite antigen. It has also been demonstrated that an intact T-cell response, specifically, appropriate interleukin-12 (IL-12) and IFN-γ production, is necessary for resistance against either *N. caninum* or *T. gondii*. The parasite may therefore facilitate further infection by compromising host immune responses.[911] Recent evidence suggests that neuropeptides called neuroimmune proteins (NIPs) are released from the CNS when an animal is stressed, which may lead to suppression of lymphocyte production and function.[912] Stress leads to high circulating glucocorticoid concentrations, which are also immunosuppressive.[912] The combination of high resting concentrations of glucocorticoids and an increase in NIP release may result in immunosuppression and facilitate development of clinical disease in horses infected with *S. neurona*. Recent evidence from a controlled investigation at OSU demonstrated that health events before diagnosis of EPM were strongly associated with the disease.[797] Transport stress and induction of the disease in an experimental equine model provide supporting evidence that stress may play a role in the pathogenesis of EPM.[863] It has long been known that transport is a stressor in horses and other species.[913–917] Horses are transported year-round to equestrian events in the United States, sometimes across the country and to other countries. Further controlled investigations are needed to examine the role of stress in the development of clinical signs of EPM in horses.

35.2.28.6

Diagnosis

The diagnosis of EPM has been difficult because of a lack of understanding regarding its pathogenesis and the variety of clinical signs. Postmortem examination was the first method used to diagnose EPM definitively, and many still consider it the “gold standard” for diagnosis. Grossly, the CNS lesions identified postmortem are described as multifocal areas of hemorrhage to light discoloration of the brain or spinal cord.[843] Histology often reveals a marked mononuclear perivascular cuffing with necrosis and loss of neurons, with infiltration of monocytes, lymphocytes, some eosinophils, and rarely, neutrophils.[802,835] Protozoan organisms can be seen in some of the lesions but are often difficult to detect.[835] Difficulty in detecting the organisms increases if the animal has been treated with antiprotozoal medications.[918] Immunohistochemical

staining techniques can be used to identify parasites definitively in situ.[919,920] Postmortem examination is also the definitive diagnostic test for EPM caused by *N. caninum (N. hughesi)*.[840] Inmmunohistochemistry is also a useful tool for identification of the *Neospora* organisms.[840] However, a significant problem with this diagnostic method is that, by definition, it cannot be applied in horses antemortem and therefore cannot be applied to most clinical cases. A reliable diagnostic test that can be used for antemortem diagnosis is needed to better understand EPM and appropriately manage horses with this disease.

35.2.28.7

Epidemiology

Little is known about the epidemiology of EPM, although more and more knowledge is being accumulated about this disease.

A small study from one county in Pennsylvania indicated that the seroprevalence was approximately 45% of the horse population (95% confidence interval, 36.3% to 54.3%), and prevalence increased with age.[921] Another report found an overall seroprevalence of 45% among horses in Oregon, with differences in seroprevalence among geographic regions.[858] In Oregon the seroprevalence ranged from 22% in the eastern arid region of the state to 65% in the coastal region. A third study reported a 53.6% prevalence of serum antibodies to *S. neurona* in Ohio horses.[922] The Ohio study demonstrated an increase in prevalence with age of the horse, and greater prevalence in southwestern Ohio versus northeastern Ohio. The geographic differences in Ohio may have been related to climatic differences and freezing days in various regions of the state.[922] These studies suggest that in many areas of the United States, approximately 50% of the horses may have serum antibodies to *S. neurona*.[923] Another study suggested horses are exposed to *S. neurona* in the eastern half of the United States at a rate 10% to 15% higher than the exposure rate in the western half of the country.[832] More recently, antibodies to *S. neurona* were found in 33.6% of various equid serum submitted to a laboratory in Colorado. As previously reported, the prevalence increased with age; prevalence was 26% in horses age 1 to 5 years versus 37% in 10-year-old horses.[924] Seroprevalence was lowest during the colder months, as reported previously. Another report on seroprevalence of *S. neurona* in horses demonstrated 27% in California, 28% in Florida, 54% in Missouri, 0% in Montana, and 0% from New Zealand.[925] A Michigan study indicated a seroprevalence of 60%, with lower rates in colder areas, which corroborates earlier findings.[926] Another study tested two populations of horses for *S. neurona* antibodies: the wild horse population in Wyoming and horses from western Canada.[927] Using the WB test yielded 18 of 276 Wyoming horses positive and 0 of 243 Canadian horses. These results are difficult to interpret in the Wyoming horses because of the range of the opossum; the Canadian results fit with its range. Two recent reports suggest that the seroprevalence of *S. neurona* antibody in horses in Argentina and Brazil are 35.5% and 35.6%, respectively.[784,785] Another recent study examined *S. neurona* exposure in Brazilian horses using an rSnSAG4 ELISA, resulting in a seroprevalence of 69.6%.[928] Another study examined American-born horses exported to India for *S. neurona* exposure.[929] Of the 86 horses tested in this study, 42 were still positive, even though some of the horses had been in India for 13 years. This work suggests that antibody to *S. neurona* has an extremely long half-life, or that chronic infection occurs with this parasite.

These results suggest that exposure to *S. neurona* is common, but that geographic differences may exist.

Little work has been performed regarding the prevalence of antibody to *N. caninum/N. hughesi* in horses. However, recent work found a seroprevalence of 23.3% in sera examined from two U.S. horse slaughterhouses and a lack of antibody detection in Argentina and Brazil.[784,785,930] Because of the low

numbers of horses involved, these studies may not reflect the true prevalence of *N. caninum/N. hughesi* antibody in horses. A more recent study found seroprevalence to *Neospora* of 2% to 3% in Missouri and California.[925] Antibodies to *N. caninum* were found in 31.1% of Wyoming horses.[927] However, testing of the Brazilian horses using the rNhSAG1 ELISA demonstrated a seroprevalence rate of 2.5% for *N. hughesi*.[928] Based on these varying results, More work is needed regarding *N. caninum/N. hughesi* exposure.

No formal studies on the incidence or prevalence of EPM in the United States have been done until recently. Based on the number of cases diagnosed postmortem at the University of Kentucky, the incidence of EPM may be increasing.[846] The number of samples submitted for immunoblot analysis suggests that several hundred new cases of EPM might be diagnosed in the United States each year.[846] The estimated incidence of EPM based on accessions to the University of Kentucky diagnostic laboratory was 1% or less of all horses each year.[843] The number of U.S. cases has only recently been enumerated by the U.S. Department of Agriculture (USDA), which provide a baseline for future reference. Based on the USDA study, the average incidence of EPM was 14 ± 6 cases per 10,000 horses per year.[931] The incidence was examined based on primary use of the horse in the operation, and the lowest incidence was found in farm/ranch horses (1 ± 1 cases/10,000 horses/year). Incidence in pleasure horses increased to 6 ± 5 cases/10,000 horses/year. A marked increase followed in breeding horses (17 ± 12 cases), racing horses (38 ± 16 cases), and competition/show horses (51 ± 39 cases). The racing horses did not include horses at racetracks. These estimates reflect a similar incidence of EPM as previously reported, if not lower, and provide a baseline for the future.

1014

1015

Regarding the incidence of neosporosis in horses, no controlled investigations have been performed. There have been six reports of neosporosis in horses caused by *N. caninum (N. hughesi)*.[778–783] However, only four cases were in horses with neurologic signs, one was in an aborted fetus, and one was related to an intestinal problem.

Equine protozoal meningoencephalitis has been reported from a number of U.S. states, as well as from Canada, Mexico, Panama, Argentina, and Brazil.[784–790] EPM has also been reported in England among horses imported from the eastern United States.[794] EPM was diagnosed in an 8-month-old Arabian horse in South Africa that had been imported from the United States approximately 5 months before the onset of signs.[793] The most recent report was a California horse that developed clinical signs of EPM after 10 months in Hong Kong.[792] An American-born horse developing EPM has also been reported in Japan.[791] Neurologic disease has been reported in horses in France, both American-born horses and horses native to France.[795,796] EPM is thus primarily a disease of the Western Hemisphere.

Several authors have suggested prevalence of disease may be high among standardbred horses.[801,802,918,932] However, two of these authors also suggested that this apparent predilection may be caused by the environment in which horses were kept rather than breed characteristics.[801,918] Another case series reported that disease was most common in thoroughbreds.[788] A controlled investigation into risk factors for development of EPM did not find a breed predilection, but occupations such as racing and showing demonstrated increased risk compared with breeding and pleasure horses.[797] This finding was corroborated by the recent National Animal Health Monitoring System (NAHMS) study.[931]

Early reports on EPM suggested that young horses had an increased risk of disease.[788,802,918] A consistent theme among reports was that at least 60% of the affected horses were 4 years old or younger. An OSU study

also found increased risk in young horses, although increased risk was seen in horses older than 13 years as well.[797]

Historically, EPM has been reported as a "sporadic" disease; more than one case is rarely reported on farms.[801,933] In reports of EPM cases from Panama, all affected horses were stabled at the same location, although this is not a common occurrence.[787] Also, an outbreak was reported on a farm in Kentucky.[934] An Ohio study suggested an increased risk for EPM if the disease was previously diagnosed on the farm (>2.5 times higher), which suggests clustering of cases may occur.[797]

Several other risk factors for development of EPM have been reported. The Ohio study found an increased risk if opossums were seen on the farm and with the presence of woods on the farm, seasonal effect, or a health event before development of clinical signs of EPM.[797] The seasonal effect increased the risk of EPM as the temperature increased, with the highest risk in the fall.[797] Risk decreased if a creek or river was present on the farm and if the feed was kept protected from wildlife access.[797] The NAHMS study found an increased risk if opossums were seen (vs. never seen) on the premises and even higher risk if the opossums were seen frequently.[931] Risk also increased with increased numbers of horses, purchased versus homegrown grain, use of wood chips or shavings as bedding, presence of rats and mice on the premises, and increased human population density. A lower risk was seen when woods were within 5 miles of the premises and when surface water was used as the primary drinking source. As in the Ohio study, the highest risk for disease was in the fall of the year. It is difficult to explain some of the findings from these studies, but management apparently plays a role in development of clinical EPM.

Recent results demonstrate that transplacental transmission of both *S. neurona* and *N. hughesi* is unlikely. After following horses at three breeding farms in California and one farm in Kentucky, investigators concluded that there was no detectable risk of transmission of either parasite.[935]

35.2.28.8

Treatment and Prognosis

Because of the slow development of a consistent equine model for induction of EPM, and because clinical patients require medication due to the severity of the disease, treatment regimens have evolved empirically. Until recently, recommended therapy had not changed since EPM was originally identified. However, recent use of liquid combination therapies with questionable stability resulted in a lack of response and consistently longer duration of treatment. This has led to the development of novel treatments.

The standard therapy for horses with EPM is a combination of sulfadiazine and pyrimethamine, both antifolate medications. Based on the description of the pathologic lesions of EPM and identification of organisms that resemble *T. gondii,* the first recommendations for treatment of EPM were extrapolated from therapy used to treat toxoplasmosis in humans.[936,937] Numerous changes have since been made with regard to dosage and duration of the therapy.[896,933,938,939] Most recommendations were empirically based on clinical impressions rather than controlled clinical trials.[896] More recently, some therapeutic recommendations have been based on pharmacokinetic data.[940,941] One study tested pyrimethamine, trimethoprim, sulfonamides, and combinations of these drugs against *S. neurona* merozoites in tissue culture.[942] Pyrimethamine was demonstrated to be completely inhibitory and coccidiocidal at 1.0 μg/mL. The same was true for trimethoprim at 5.0 μg/mL. None of the sulfonamides alone had activity at 100 μg/mL. Sulfonamides (5.0 or 10.0 μg/mL) in combination with pyrimethamine (0.1 μg/mL) improved activity against

S. neurona.[942] However, these findings are based on in vitro studies, and further work is needed in controlled clinical trials in horses. Controversy surrounds the duration of therapy required to treat horses with EPM effectively; initially, recommendations were based on clearing of specific IgG from the CSF, as indicated by a negative WB. However, many horses remain CSF positive for antibody to *S. neurona* for months after therapy. Many clinicians have adopted the recommendation that the medications be continued at least 2 weeks after resolution of signs or 4 weeks after a plateau of the clinical signs. Current recommendations for the pyrimethamine/sulfadiazine combination is 20 mg/kg of sulfadiazine once or twice daily and pyrimethamine at 1 mg/kg daily orally for at least 150 to 180 days. Horses with EPM are often treated for long periods with medications that act by inhibiting folate metabolism. Some suggest that complete blood counts should be monitored for signs of folic acid deficiency in horses treated for EPM. Potential side effects of treatment with antifolate medications include bone marrow suppression, anemia, colitis, and even teratogenesis. Most of the anemias are mild and improve after withdrawal of the medication. One other side effect of trimethoprim-sulfamethoxazole and pyrimethamine, a commonly used combination in the past, is its effect on reproductive function in pony stallions.[943] Although it may not affect semen quality, testicular volume, sperm production efficiency, erection, or libido of healthy stallions, it may induce changes in copulatory form and agility and alter the pattern and strength of ejaculation.[943] Therefore, caution should be used when treating stallions for neurologic disease believed to be EPM.

1015
1016

Recently, triazine derivatives have been used to treat EPM. Two of these drugs, diclazuril and toltrazuril, were originally designed for use as herbicides and have been used in other countries in the prophylaxis of coccidiosis in poultry and swine. The response to therapy in horses with EPM was slightly better than the response documented for the standard therapy.[944] The pharmacokinetics of both diclazuril and toltrazuril have been demonstrated.[945] Currently, diclazuril is only available as a ration premix, so large volumes must be given daily. Another disadvantage is the poor palatability of diclazuril in its present form. One advantage to use of these compounds is an appreciably shorter duration of therapy. Diclazuril is administered at 5 mg/kg for a minimum of 28 days.[946] Recent in vitro testing for activity of diclazuril against *S. neurona* has been demonstrated.[947] Diclazuril may need to be administered by nasogastric tube daily.[946] Toltrazuril is another coccidiostat becoming increasingly popular because of its ease of use and good absorption orally in horses.[948] Toxicity studies of toltrazuril in horses at 50 mg/kg for 10 days resulted in mild anorexia and depression.[949] The current recommended dose is 5 to 10 mg/kg for a minimum of 28 days.[946] Further in vitro evidence indicates that ponazuril, a metabolite of toltrazuril, is effective against *S. neurona*.[950]

Nitazoxanide (NTZ) is another novel treatment recently used in the treatment of EPM. NTZ is a 5-nitrothiazole with a broad spectrum of activity against bacterial, protozoal, and helminthic parasites.[946] It has been shown to kill *S. neurona* in cell culture.[946] Toxicity studies showed that when horses were given two times the recommended dose, they became lethargic after 1 week of daily dosing.[946] When horses were given NTZ at four times the recommended dose, they became significantly ill, with one death.[946] At present, the suggested dose schedule is 25 mg/kg once daily for the first week and 50 mg/kg once daily for the next 23 days.[946] Two of these three new EPM medications, Marquis and NTZ, have been approved by the U.S. FDA.

The prognosis for horses diagnosed with EPM is similar regardless of the treatment used. Most reports suggest an approximate improvement rate of 70% when using the standard therapy,[804,951,952] but earlier work suggested the success rate of therapy was about 50%.[939] Less than 25% of affected horses may return to their original function, although little objective information exists on this issue.[804] A recent study with

diclazuril resulted in approximately 75% improvement in horses severely affected with EPM.[944] In the diclazuril study, approximately 30% of the horses (11/36) treated either returned to their original level of performance before EPM diagnosis or improved their level of performance.[944] An efficacy study of 70 horses given NTZ found 63% of the horses met the criteria for success after treatment.[946] A growing concern is the percentage of horses which have a relapse in clinical disease after cessation of therapy. Some horses will relapse days, weeks, or even months after cessation of therapy, but the mechanism of relapse is unknown.[896] Relapse may be caused by recrudescence of a truly latent stage of the parasite, presence of a small, persistent focus of infection, or perhaps reexposure to the parasite.[896] Anecdotal estimates of the relapse rates range from 10% to 28% of treated horses.[804,951,952] In a controlled study performed at OSU, relapse rates were 19%, close to previous anecdotal reports.[953] The relapse rate using diclazuril for the treatment of EPM was less than 5%.[944]

Identification of protein activity in *S. neurona* merozoites has demonstrated two potential targets for therapy, including serine protease and enolase.[954,955] In the future, better treatments might be developed against certain proteins to remove or reduce relapse rates and improve the resolution of clinical signs of EPM.

Before recognition of EPM, corticosteroids were widely recommended for treatment of neurologic diseases in horses. However, corticosteroids should be used with caution in horses with suspected EPM because the host immune response to the organism could be adversely affected.[789,794,936,937] NSAIDs and DMSO have also been routinely used in the treatment of horses with EPM since the mid 1980s.[794,804]

Because antibody to *S. neurona* persists in CSF for long periods in some horses with EPM, and because some horses may not mount a sufficient immune response to clear the organism, immune stimulants (nonspecific T-cell—stimulating compounds) have been recommended.[804] Unfortunately, no controlled trials have examined the efficacy of these treatments.

Supplementation with folic acid, folinic acid, and brewer's yeast has been recommended for treatment of presumed folic acid deficiency, particularly in pregnant mares.[794,939] However, folic acid supplementation has been discouraged by other investigators because of poor absorption and the potential for toxic effects on bone marrow activity.[804] Toxicity has also been reported in newborn foals born to mares that were treated for EPM with antifolate medications and concurrently supplemented with folic acid.[956] These foals showed evidence of bone marrow aplasia and hypoplasia, renal nephrosis or hypoplasia, and skin lesions. Another case report involved an adult horse being treated for EPM.[957] A cause-and-effect relationship between folic acid supplementation and these developmental abnormalities has not been conclusively demonstrated. At present, however, folic acid supplementation should not be used, particularly in pregnant mares, until controlled clinical trials can be performed to corroborate or refute these findings.

Use of additional supplements, such as vitamin E and thiamine, that may facilitate healing of nervous system tissue have been recommended for treating horses with EPM.[804,951] However, clinical trials have not been performed to establish the efficacy of this supplementation.

35.2.28.9

Prevention

Based on the proclivity for transportation to equestrian events and the nature of the horse business, prevention of clinical cases of EPM will be difficult. A complicating factor is that the parasite is widespread

throughout much of the United States. A killed—*S. neurona* vaccine was developed and released on a conditional license in 2000. The vaccine has been shown to induce both humoral and cell-mediated immunity in the horse.[958] However, efficacy of the vaccine to prevent EPM using an equine model have not been completed to date. Because development of other parasite vaccines is extremely difficult, efficacious vaccines most likely will not be developed for many years.[949–962]

1016

1017

Based on age as a risk factor for the disease, close monitoring for evidence of neurologic disease in high-risk age-groups (young horses, old horses) may help detect EPM early. The seasonal risk for EPM should raise the index of suspicion that it may be the cause of the clinical signs when horses are presented for neurologic disease in the warmer months. This seasonal risk factor is compounded by many major horse competitions occurring in the fall. Therefore, monitoring of horses subsequent to transport and competition may be helpful. Access to feed and water by wildlife (opossums) and pests (mice, rats) should be restricted by using rodent-proof containers, which may help to prevent some cases of EPM. Forages should also be protected from wildlife access by keeping the forages in enclosed facilities to prevent access to opossums.[797] Some research suggests that preventing bird access to facilities may help to prevent some cases of EPM, although it is not known what role birds may play in its pathogenesis. Ingesting sporocysts may result in passage through the intestinal tract of birds and may be infective for other species of wildlife or horses.[904,905] Horses may develop EPM after some other health event, as confirmed by a recent controlled investigation.[797] Therefore, monitoring of broodmares close to foaling and horses that develop a major illness or injury is important because it may assist in the early diagnosis of EPM cases.

Focusing prevention on manipulation of risk factors for the disease, such as keeping opossums out of the feed and water, is very important. However, one also must consider the intermediate host's role in EPM. As discussed previously, several species of mammals have been reported to act as natural or laboratory intermediate hosts in the life cycle of *S. neurona*.[872,891–893] These animals are not a threat unless they are dead. Therefore, veterinarians should encourage horse owners to pick up dead cats, armadillos, skunks, and raccoons on their property. It is important to dispose of the carcass so that opossums cannot eat them and excrete more infectious organisms to infect horses. Picking up these carcasses should be done carefully with an inverted plastic garbage bag, plastic gloves, or some other instrument.

These protozoan parasites are extremely difficult to kill in the environment. A recent study tested the most common disinfectants used in veterinary medicine, including povidone-iodine, chlorhexidine, formalin, two different strengths of NaOH, and high-temperature steam.[963] The *S. neurona* sporocysts thrived on the disinfectants and the lower concentration of NaOH. At the higher concentration of NaOH, the parasites did not survive the treatment, however, most barn materials could not withstand this agent. The parasite could not withstand temperatures of 60°C (140°F) for 1 minute or higher temperatures for shorter periods. Therefore the only alternative for cleaning horse facilities is use of steam.

Recently, medications to prevent development of clinical signs in IFN-γ/KO mice and in horses were attempted. The first study used pyrantel tartrate, a daily anthelmintic prophylactic treatment, and concluded that it does not prevent *S. neurona* infections in mice.[964] A similar study in horses tested for seroconversion in serum and CSF and days to seroconversion.[965] There was no difference in the groups receiving and those not receiving pyrantel. Another study used the triazine-derivative anticoccidial diclazuril;* mice treated before or up to 7 days after infection did not develop clinical signs, and no parasites were recovered from the mice.[966] This study suggests that anticoccidial drugs may be useful in the prevention of *S. neurona* infections in animals. A second triazine derivative, ponazuril, was tested in IFN-γ/KO mice.[967] A single dose prevented

abnormal neurologic signs and death, depending on when it was administered. This further corroborates the potential for prevention of EPM using anticoccidial drugs. In a further study on prevention of EPM in horses, two dose ranges of ponazuril were administered daily based on the recommendations for treatment; 71% of horses given 2.5 mg/kg and 40% given 5 mg/kg developed neurologic deficits.[968] Seroconversion was decreased in the 5-mg/kg group compared with the controls. Therefore, this study needs to be repeated to attempt other doses of ponazuril for prevention of clinical signs of EPM, because coccidiostats may be one method of prevention useful in the future.

* Clinicox, Schering-Plough Animal Health Corporation, Union, NJ.

35.2.29

BABESIA ENCEPHALITIS (BABESIOSIS; PIROPLASMOSIS; TEXAS CATTLE FEVER; TICK FEVER; REDWATER)

Parasitemia of cattle caused by the protozoans *Babesia bovis, Babesia argentina,* and *Babesia bigemina* usually is subclinical but results in devastating economic losses worldwide.[969] The disease is transmitted to cattle by the cattle fever ticks *Boophilus annulatus, Boophilus microplus,* and *Boophilus decoloratus*. Babesiosis occurs in the Americas, Europe, Africa, Asia, and Australia. Ticks acquire *Babesia* infection from an infected animal and then pass the agent to their offspring through the ovaries. The protozoan is passed to susceptible cattle by nymphs and adults. Most infections result in intravascular and extravascular hemolysis and kidney and liver failure. A small proportion of *Babesia* infections cause acute encephalitis.[970,971] The CNS signs begin suddenly and include fever (41.7°C [107°F]), anorexia, depression, ataxia, conscious proprioceptive deficits, mania, convulsions, and coma. Sudden death occasionally is observed. The nervous system signs are accompanied by engorgement of the scleral vessels, icterus, proteinuria, and hemoglobinuria. Encephalopathic diseases that closely resemble babesiosis include rabies, coccidiosis, polioencephalomalacia, lead poisoning, infectious bovine rhinotracheitis virus encephalitis, theileriasis, heartwater disease, salt poisoning, and chlorinated hydrocarbon toxicity.

The pathogenesis of the CNS signs is unclear; however, possible causes include capillary thrombosis and infarction, disseminated intravascular coagulation (DIC), anoxic encephalopathy, and direct invasion of the CNS by the parasite. Thrombi are disseminated throughout the CNS. Expression of parasite proteins on the surface of infected red blood cells (RBCs) facilitates binding of RBCs to capillary endothelial cells.[972] The proclivity of *Babesia*-infected RBCs for binding to brain capillaries, particularly those in the cerebellum, is supported by the high incidence of parasite-positive RBCs found in the brains of infected cattle.[973] These findings and the observation of increased prothrombin and partial thromboplastin times, thrombocytopenia, and decreased fibrinogen concentrations suggest that DIC may play a role in the pathogenesis of the CNS disease.[974–976] Vascular blockage in the CNS, caused by severe sludging of RBCs within brain capillaries, appears to be central to the pathogenesis of neurologic disease in infected animals.[977] Studies of *Babesia ovis* in sheep, in which neurologic disease did not occur, failed to demonstrate RBC blockage of brain capillaries.[978] This further supports the belief that CNS vascular pathology is key to the development of neurologic signs in bovine babesiosis.

Babesia encephalitis is a reportable disease in the United States. Suspect cases should be referred to the appropriate state and federal authorities.

35.2.30 *EHRLICHIA (COWDRIA, RICKETTSIA) RUMINANTIUM* INFECTION (HEARTWATER DISEASE)

35.2.30.1 Definition and Etiology

Ehrlichia ruminantium is a rickettsial parasite that causes a fatal encephalitis in goats, sheep, and cattle.[979] The disease originated in sub-Saharan Africa and has spread to cattle in the West Indies (Guadeloupe, Antigua, and Marie Galante),[980] where it has become an economically important tick-borne disease of cattle. *E. ruminantium* is transmitted by *Amblyomma* ticks.[981,982] Although a number of *Amblyomma* species have been implicated in the transmission of heartwater disease, the most important agents are *A. hebraeum* and *A. variegatum*. The intermittent feeding behavior of the tick makes it particularly resistant to treatment with acaricides. *Amblyomma* ticks require three separate blood meals to complete their life cycle. The gravid females fall from the host and lay the eggs in rotting vegetation, particularly in areas where the hosts are bedded for the evening. Recently hatched larvae crawl onto foliage and await a host. After their first feed the larvae detach, molt into nymphs, and await a second host. After refeeding the nymphs detach and molt into adults. The adults remain under rotting vegetation until they are activated by carbon dioxide exhaled by a large mammal. They are further attracted to the host by pheromones from male ticks that remain permanently attached to the host. Animals that do not have male tick infestations are poor attractants for nongravid females. Once attached to the proper host, the females seek the male, breed, feed, and fall from the host when it lies down for the evening. Ticks that feed from *Ehrlichia*-infected hosts develop ovarian infections and transmit the agent to their offspring. This serves to perpetuate the agent over successive seasons.[983]

Many species of vertebrates, including snakes, iguanas, lizards, and birds, are reservoirs for *E. ruminantium* because these animals may serve as the first two hosts for the *Amblyomma* tick.[984] A vector-wildlife cycle facilitates the survival of *E. ruminantium* even when domestic livestock are absent from the environment.[985]

35.2.30.2 Clinical Signs

Animals with the peracute form of *E. ruminantium* infection die suddenly without premonitory signs. The acute form of the disease is characterized initially by fever, anorexia, depression, and respiratory distress. Cyanosis also may be noted. Nervous system signs, which may appear within a few days, include hyperesthesia, snapping closure of the eyelids, rapid extension of the tongue, behavioral changes, muscular fasciculations, hypermetria, ataxia, conscious proprioceptive deficits, and head pressing. As the disease progresses, the animals become recumbent and comatose. Convulsions may occur terminally. These episodes are characterized by opisthotonos, nystagmus, chewing movements, and frothing at the mouth. Mild forms of the disease are characterized by transient diarrhea, malaise, and fever, with no CNS involvement. The mortality rate in sheep ranges from 6% to 80%. Animals that recover are immune to reinfection for at least 58 months.[986] Losses may reach 60% of susceptible cattle and 40% of goats. The mortality rate among Angora goats may exceed 90%.

35.2.30.3 Pathophysiology

After inoculation into a ruminant, the rickettsial agent infects reticuloendothelial cells and proliferates by binary fission within membrane-bound vacuoles.[987,988] Release of the parasite from degenerating

macrophages and neutrophils causes successive waves of parasitemia that infect endothelial cells and cause vasculitis.[988,989] In the cell the developmental stages of the *Ehrlichia* organism resemble those of chlamydia and include elementary, reticulate, and intermediate bodies, which can be differentiated microscopically.[990] Nervous system lesions may be caused by permeability changes in the cerebral capillaries. Changes in the other soft tissues include hydropericardium, hydrothorax, and subcutaneous edema.[979]

Except for Angora goats, which are highly susceptible to *Ehrlichia* infection, animals reared in indigenous areas usually have a high level of immunity and do not succumb to the infection.[991] Animals that survive the initial infection become asymptomatic but remain rickettsemic for as long as 223 days (sheep), 246 days (cattle), and 8 days (goats). Calves under 3 weeks of age, lambs under 8 days of age, and kids under 6 weeks of age are inherently resistant to *E. ruminantium* infection, regardless of the amount of colostral protection they have received.[992,993]

35.2.30.4 Necropsy Findings

Pathologic changes of heartwater disease include hydropericardium, hydroperitoneum, hydrothorax, pulmonary edema, perirenal edema, hemorrhages in the pleura and peritoneum, and hemorrhagic enteritis. Microscopic changes include microgliosis, necrotizing vasculitis in the brain, hemorrhage, edema of the neuropil, microcavitation, and focal necrosis of the granular layer of the cerebellum. In clinical cases the parasite can only be definitively diagnosed by biopsy of the cerebral cortex or by collection of the cortical tissues at postmortem examination.[994] Simple techniques for collection of such biopsy specimens have been described.[995–997] Squash preparations of the biopsied material should be stained with either methyl green pyronine or Giemsa stain before microscopic examination of the tissues.[998,999] A cloned DNA probe that identified *E. ruminantium* DNA has been developed, but the clinical usefulness of the test is unknown.[1000]

Diagnostic tests developed to identify infected livestock include an indirect fluorescent antibody (IFA) test using infected bovine aortic endothelial cells for indicators, several ELISAs, and tests using PCR methodology.[1001–1004] Of these, PCR is the most accurate.

35.2.30.5 Treatment

The administration of oxytetracycline (6 to 10 mg/kg IV twice daily for 3 or 4 days) may be beneficial for treatment of the early stages of the disease. The long-acting formulation of oxytetracycline also is effective, but for best results it should be administered as soon as the animal becomes febrile. Addition of dimethyl sulfoxide (DMSO) to the treatment regimen may be helpful: DMSO improved respiratory function in *E. ruminantium*—infected sheep, although it reduced their appetites.[1005] Treatment usually is futile if the first dose of oxytetracycline is administered after the onset of neurologic symptoms.[1006] Despite the depository nature of the long-acting formulation, two or more doses 48 hours apart are needed to achieve a good clinical response. Cattle should be re-treated if they develop a fever after the first dose has been administered.[1007] Animals with nervous system signs frequently die despite intensive antibiotic therapy. Angora goats are highly susceptible to heartwater disease. In South Africa, Angora producers routinely treat all animals every 14 days during the summer with oxytetracycline. Nevertheless, the number of deaths caused by heartwater disease is directly related to the number of antibiotic treatments administered. Animals that remain essentially tick free never develop adequate immunity to the *Ehrlichia* organism.

A small degree of tick infestation and exposure of the animals to low numbers of the agent, combined with judicious oxytetracycline therapy, would seem to favor the development of immunity over time.[1008] One method of immunization uses a controlled infection of a virulent strain (Onderstepoort Ball 3 strain) of the *Ehrlichia* organism and treatment with long-acting oxytetracycline (800 mg per adult goat) at the beginning of clinical disease and 10 days later.[1009] Vaccination with this isolate produces immunity against exposure to homologous but not heterologous strains of *Ehrlichia*.[1010–1012] More recent strategies have included vaccines utilizing inactivated organisms, live attenuated organisms, and fragments of *E. ruminantium* nucleic acid, but none has had great success.[1013–1017]

1018

1019

35.2.30.6 Prevention and Control

Control of ticks on cattle pastures is the most desirable means of controlling heartwater disease. Complete eradication of the ticks in most regions of sub-Saharan Africa is neither possible nor desirable. Cattle that are reared in areas where *Ehrlichia* infection is endemic develop acquired immunity over time. In these areas the ticks should be sufficiently abundant to permit a low level of heartwater infections in most cattle, yet not so populous as to introduce severe, overwhelming infections. Integrated methods for tick control have been recommended. These include exclusion of wildlife from paddocks, artificial induction of host resistance to ticks, application of insecticidal ear tags, and conventional acaricide application. Application of insecticides as the sole method of tick control has not proved highly effective. Resistance to the acaricides may develop with prolonged use. The dips are expensive and frequently are used at improper concentrations. Moreover, some species are not highly attracted to ruminants unless other ticks are already attached. Treatment of these animals would be ineffective and wasteful. A novel osmotic pump loaded with ivermectin that delivers 60 µg/kg/day kills *Amblyomma hebraeum* and reduces the number of fertile eggs shed. Data on the efficacy of the drug under field conditions have not been published.

35.2.31 CEREBRAL THEILERIASIS (TURNING SICKNESS; DRAAISIEKTE; EAST COAST FEVER; CORRIDOR DISEASE; JANUARY DISEASE; TROPICAL FEVER)

35.2.31.1 Definition and Etiology

Cerebral theileriasis is an encephalitic disease of cattle caused by the piroplasma parasites *Theileria annulata* and *Theileria parva*.[1018,1019] Theileriasis is seen mainly in Africa (Kenya and Tanganyika) and India, where it is characterized by a high mortality rate and is known as East Coast Fever. *Theileria sergenti* is found in Korea and Japan. *Theileria mutans,* a parasite of cattle in the southwestern United States, is relatively nonpathogenic.[1020] A mild form of theileriasis, locally called “January disease,” occurs in cattle in Mozambique. This condition is caused by the subspecies *Theileria parva bovis*. Corridor disease is caused by *Theileria parva Lawrence,* and *Theileria annulata* is the cause of Mediterranean Coast fever or tropical theileriasis. Other species associated with cerebral theileriasis include *Theileria mutans* and *Theileria taurotragi*.[1018]

East Coast fever probably originated in buffalo in eastern Africa and later spread to cattle. Spread of the disease to southern Africa probably occurred through introduction of infected cattle from eastern Africa. European breeds of cattle *(Bos taurus)* develop a more severe disease than do comparably infected Indian breeds *(Bos indicus)*. Both types of cattle appear to be equally susceptible to infection, but differ in their

ability to control the course of disease.[1021] *Theileria* organisms are transmitted to susceptible cattle by the ticks *Hyalomma anatolicum, Hyalomma lusitanicum,* and *Amblyomma hebraeum.*[1022]

Trypanosoma species manipulate the immune system both to evade destruction and to promulgate infection. Organisms escape the host immune response by altering immune system activation so that infected cells avoid recognition and destruction.[1023–1025] Clonal expansion of infected lymphocytes is promoted, and these cells disseminate throughout the body.[1026]

35.2.31.2 Clinical Signs

The clinical signs of *Theileria* infections include lymphadenopathy, nasal discharge, lacrimation, tachycardia, fever, subcutaneous edema of the face, gangrenous dermatitis, sloughing of facial skin, dyspnea, pallor, CNS disorder, and emaciation.[1027] The neurologic syndrome is characterized by ataxia, hypermetria, conscious proprioceptive deficits, depression, head pressing, hyperesthesia, blindness, nystagmus, circling, and aggressiveness. Terminally the animals become recumbent and develop opisthotonos, tonic-clonic seizures, and coma. In rare cases the parasite may localize in the spinal cord. The CNS signs result from vasculitis and lymphocytic inflammation of the brain.[1028–1030] Clinically recovered animals become persistently infected.

35.2.31.3 Necropsy Findings

The postmortem lesions of theileriasis include capillary engorgement, scattered punctate hemorrhages on the surface of the brain, thrombosis of the meningeal vessels, hemorrhage in the cerebral ventricles, pulmonary edema, peripheral lymphadenopathy, and infarctions of the kidney and spleen. The brain of affected animals appears to have a yellow hue.[1030] Microscopically, blue cytoplasmic inclusion bodies (Koch's blue bodies) are seen in the lymphocytes adjacent to the hemorrhagic areas.

The nervous form of theileriasis is difficult to diagnose definitively because the parasite is only sporadically visible in sections of nervous tissue from the infected animals. Parasitemia occasionally can be detected by microscopic examination of blood smears from infected calves. Reliable blood tests currently are not available. Biopsy of the cerebral cortex has been recommended as a confirmatory test for the disease. The CSF of affected animals is normal or has an increased protein concentration ranging from 1400 to 12,452 mg/dL, with normal numbers of white blood cells.[1029]

35.2.31.4 Treatment

Parvaquone (Clexon),* 10 to 20 mg/kg intramuscularly (IM) in two injections 48 hours apart, and buparvaquone (Butalex),† at a single dose of 2.5 mg/kg, are approximately 90% effective for the treatment of theileriasis.[1031] Some studies have found buparvaquone to be the most effective treatment.[1032,1033] Parvaquone can be combined with furosemide, which improves survival of cattle that develop pulmonary edema, a common consequence of theileriasis.[1034] Menoctone (10 mg/kg IV or IM) also is curative. Single doses were effective, but repeating the treatment daily for 5 days eliminated posttherapeutic recrudescence.[1035] The disease is exotic to the United States.

* Coopers Animal Health, Mundelelin, IL.

† Burroughs-Wellcome, United Kingdom.

35.2.31.5 Prevention

Prevention of *Theileria* infection has largely been based on the use of live attenuated vaccines, which produce a solid, cell-mediated immunity.[1036] These vaccines are used in an "infection and treatment" manner, whereby vaccination must be combined with administration of long-acting tetracyclines.[1037] Recent efforts at vaccine development have focused on the creation of subunit vaccines, using a variety of *Theileria* antigens. While promising, more work is still needed.[1038–1041] Use of vaccines, however, is still not on a large scale.

The napthoquinones are the preferred chemotherapeutic agents in vaccinated animals and include parvaquone, halofunginone lactate,* and buparvaquone (see Treatment).

* Terit, Hoescht, Germany.

35.2.31.6 Control

Tick control is vital. Weekly spraying with coumaphos and insertion of ear tags impregnated with cypermethrin (Decum)† have been effective for controlling ticks and preventing *Theileria* infections in calves in Tanzania. The calves became infected with *Theileria parva* by 3 months after the tags were removed. Woodford[1042] suggested that the intensive tick control could minimize the incidence of theileriasis until the calves could be successfully vaccinated. However, inadequate or incorrect application of products and tick resistance to chemicals present challenges to effective tick control.

35.2.32 CEREBRAL TRYPANOSOMIASIS (SLEEPING SICKNESS)

35.2.32.1 Definition, Etiology, and Clinical Signs

Trypanosomiasis is a hemoprotozoan disease of African cattle that also infects the central nervous system (CNS). The disease is transmitted to cattle by the bite of the tsetse fly (*Glossina* species). The agents that infect cattle include *Trypanosoma vivax, Trypanosoma congolense,* and *Trypanosoma brucei*. An especially severe neurologic form of the disease has been caused by the inoculation of cattle with *T. congolense,* followed 1 year later by infection with *T. brucei,* or by simultaneous inoculation with the two agents.[1043] The encephalitic signs develop 2½ to 5 months after infection and include ataxia, conscious proprioceptive deficits, knuckling, depression, circling, and head pressing. Some animals may show signs of behavioral change, lose the herd instinct, and develop hyperesthesia and constant repetitive movements. Other signs associated with progression of trypanosomiasis are semicoma, coma, recumbency, opisthotonos, and intermittent tonic-clonic convulsions, which occur 2 to 3 days before death. Affected animals are emaciated, anemic, and icteric at death.[1044]

Experimental infection with trypanosomes causes a marked fever (as high as 40.5°C [105°F]). Other common nonneurologic signs are anemia, petechiation of the mucous membranes, occult fecal blood, melena, and epistaxis. Chronic weight loss without other clinical signs may be seen in some animals.

Hematologic abnormalities include anemia, hypoalbuminemia, hyperbilirubinemia, and increased plasma concentrations of aspartate transaminase and urea nitrogen.

Acutely infected animals may develop a thrombocytopenia and prolongation of the prothrombin and partial thromboplastin times, indicating that DIC may be responsible for the vascular changes that occur before death. The anemia is characterized by increased mean corpuscular volume and mean corpuscular hemoglobin, with increased serum iron concentrations early in the infection.[1045,1046] One study did not demonstrate a change in the concentration of white blood cells or protein in the CSF of animals with the encephalitic form of trypanosomiasis.[1043] However, another study showed significant alterations in cattle infected with *T. bruceii*.[1047] These included an increase in total protein (range, 37 to 44 mg/dL) and pleocytosis (range, 0 to 3060 mononuclear cells/μL). The abnormalities in the CSF may be present in infected cattle not currently displaying clinical neurologic signs. Antitrypanosomal antibody may be found in the CSF of affected cattle using IFA tests.

35.2.32.2

Pathology

The pathologic lesions of trypanosomiasis are a nonsuppurative encephalomyelitis, serosanguineous pericardial fluid, serosal hemorrhages, pulmonary edema, centrilobular coagulative necrosis, splenomegaly, necrotizing myocarditis, and glomerulonephritis.[1048] Macroscopic lesions of the CNS include subtle thickening and grayish discoloration of the meninges. The meningeal vessels are congested. Microscopic lesions of the CNS include mild to moderate diffuse meningoencephalitis, plasmacytic and lymphocytic perivascular cuffing, nodular gliosis, and mononuclear choroiditis. The pathogenesis of the encephalitis is not understood.

Trypanosomes may be cultured from the blood and CSF of infected cattle. The number of hematogenous parasites is highest in animals with a dual infection by *T. congolense* and *T. brucei*. The clinical diagnosis of trypanosomiasis may be confirmed by inoculating blood or CSF specimens into laboratory mice and observing the recipients for parasitemia with direct darkfield examination of the patient's blood. Identification of motile trypanosomes in the buffy coat zone of a microhematocrit capillary tube using darkfield illumination apparently is the most accurate of all diagnostic methods. Trypanosomes can be differentiated by their morphologic features, manner of attachment to erythrocytes, and type of motility.[1049] Species-specific antibodies can be detected in serum using either an antigen-capture ELISA or an IFA test in which the column-purified trypanosomal antigen is fixed with acetone or formalized saline. Titers of 1:200 to 1:2000 were consistent with acute infection. The test is not typically used for field diagnosis of trypanosomiasis.[1050,1051] Infected cattle develop acquired resistance to homologous but not heterologous isolates of trypanosomes.

35.2.32.3

Treatment and Control

Of the drugs available for the treatment of trypanosomiasis, isometamidium chloride* is most often used. The recommended dosage ranges from 0.25 to 1 mg/kg IM; a single dose of 1 mg/kg exerts a protective effect for up to 6 months.[1052] The higher dosage (1 mg/kg) was required to obtain increased weight gain and prevent recurrent infection. The treatment was particularly effective when combined with weekly surveillance, followed by treatment of confirmed infected animals.[1053] Side effects of isometamidium include tachycardia, salivation, lacrimation, pollakiuria, muscle fasciculations, convulsions, diarrhea, and in

rare cases, death. The drug apparently does not cause abortion in pregnant cows or otherwise affect the calf.[1054]

Other drugs used include suramin sodium,[†] diminazene aceturate[‡] (7 mg/kg), quinapyramine sulfate and homidium chloride[§] (1 mg/kg). These drugs provide residual protection from reinfection for approximately 2 months; however, recurrent infection and resistance, especially to diaminazene, have been reported.[1055–1058] Combinations of these drugs (e.g., diaminazene followed by isometamidium) reduce the number of resistance-related therapeutic failures. Relapses also undoubtedly occur because many of the chemoprophylactic drugs are unable to penetrate the blood-brain barrier in sufficient concentrations to eliminate the parasite in the CNS tissues.

1020

1021

Because of the variable responses to treatment and the ability of *Trypanosoma* organisms to develop drug resistance, all control programs must include methods of controlling the tsetse fly.[1057] Current recommendations for fly control include application of insecticides with residual pyrethroids. Several methods of pyrethroid application have been investigated, including inclusion in a visual baited target (deltamethrin)[1059] or application of a pyrethroid pour-on formulation (Bayticol pour on, 10 mL/100 kg).[*] Both methods have been highly effective for reducing the tsetse fly population and trypanosome infection rates. Animals can be dipped in Deltamethrin dip every 2 weeks. A single application of the chemical has residual activity for as long as 52 days; however, to ensure maximum killing, application every 14 days is recommended. Because the tsetse fly prefers to feed from the ventral torso or the legs, insecticide-impregnated ear tags have been ineffective for preventing infection.[1060] Other fly control methods include aerial spraying with endosulfan, ground-based spraying with 4% dichlorodiphenyltrichloroethane (DDT), or use of scented insecticidal traps.[1059] However, cost and environmental concerns have limited the usefulness of these techniques.

Selection of resistant lines of cattle is possible. The taurine N'Dama and West African shorthorn breeds have innate resistance to trypanosomiasis and are the sole breeds of cattle in areas of tsetse fly range.[1061] Resistant breeds of small ruminants include the Djallonke, Red Maasai, Blackhead Persian, and East African sheep and goats.[1062] Imported breeds of livestock usually cannot be maintained, even in areas of low tsetse fly risk, without intensive drug therapy.[1063]

35.2.33

POLIOENCEPHALOMALACIA (CEREBROCORTICAL NECROSIS)

CHRISTOPHER CEBRA

GUY LONERAGAN

DANIEL GOULD

35.2.33.1

Definition and Etiology

Polioencephalomalacia (PEM) is a common and important neurologic disease of ruminants[1064,1065] with a worldwide distribution. An animal with clinical manifestations of PEM often is referred to as having “polio” or being a “sleeper” or “brainer.”

Polioencephalomalacia is a descriptive term for histologic lesions[1064,1066] that may arise from a variety of etiologies. Literally, the name means softening or necrosis (malacia) of regions of the gray matter (polio) of the brain (encephalo). Thus a definitive diagnosis of PEM requires appropriate histologic examination of brain tissue. The possible etiologies of PEM include (but are not limited to) excessive sulfur consumption,[1067–1069] presumably manifested through elevated ruminal sulfide production;[1070,1071] altered thiamine metabolism;[1072] so-called salt poisoning or water deprivation;[1073] amprolium administration;[1074–1076] the molasses-urea diet;[1077] and lead intoxication.[1078]

35.2.33.2

Clinical Signs

PEM appears to manifest both subacutely and acutely.[1064,1071] In the subacute form, signs may develop within hours or over several days. In the early stages of the disease, the affected animals detach from the herd or flock, become anorectic, and stagger. They often appear blind, walk with the head held erect, and demonstrate a slight hypermetric gait. Occasionally, affected animals are excitable and charge around their enclosure, which may present a significant hazard to the veterinarian and animal handlers. Other early signs of PEM can include diarrhea, hyperesthesia, and muscle tremors, which are most obviously observed as ear flicking or facial twitching. Progression of the condition is associated with cortical blindness, head pressing, opisthotonos, dorsomedial strabismus, miosis, repetitive chewing, profuse ptyalism, and odontoprisis[1064,1068,1079–1081] (Figs. 35-10 and 35-11). Despite the defective menace response, the animals usually have normal palpebral reflexes. Affected animals may also develop a variable nystagmus, strabismus (Fig. 35-12), and head tilt. The rectal temperature is normal unless excessive muscular fasciculations have developed. The pulse and respiratory rates are usually increased. An odor of hydrogen sulfide may be detected on the breath if the PEM is associated with excessive sulfur consumption.

Although most of these animals respond favorably to aggressive therapeutic intervention, clinical signs may progress to recumbency, tonic-clonic convulsions, and death. In facilities with certain types of fencing, such as cables, affected animals may push or press with such force that they die of asphyxiation.

Fig. 35-11 Calf with advanced signs of polioencephalomalacia showing abnormal head posture and depressed sensorium.

1021

Fig. 35-12 Abnormal pupillary angle associated with strabismus in a calf with polioencephalomalacia. Because the calf's head is tied upward, the eye has rotated ventrally, although this is actually dorsomedial strabismus.

In the acute form of PEM, animals are found recumbent and comatose.[1064,1071] These animals often experience episodic tonic-clonic convulsions, and they remain recumbent and hypertonic between seizures. The prognosis is poor for acutely affected animals or those with advanced subacute manifestations. Survivors may remain irreversibly decorticated and are culled because of poor performance, chronic anorexia and ataxia, or blindness. However, mildly affected animals may remain as productive members of the herd.

Because the clinical manifestations of PEM may be subtle and nonspecific, they can be confused with other disorders. PEM often is temporarily associated with lactic acidosis that develops after consumption of

excessive amounts of readily fermentable carbohydrates. Animals with lactic acidosis may appear ataxic and obtunded in addition to having a foul-smelling, watery stool and a distended, fluid-filled rumen. Concurrent PEM may not be diagnosed, or producers may confuse PEM for lactic acidosis or primary ruminal tympany in acutely affected animals that have remained laterally recumbent for some time.

The major differential diagnoses for PEM include enterotoxemia type D (focal symmetric encephalomalacia form), *Haemophilus* meningoencephalitis (thrombotic meningoencephalitis), coccidiosis with nervous system involvement, listeric meningoencephalitis, vitamin A deficiency, ethylene glycol poisoning, locoism, rabies, and infectious bovine rhinotracheitis encephalitis (calves only).

35.2.33.3

Clinical Pathology

Although a definitive diagnosis depends on histologic confirmation, a presumptive diagnosis may be made antemortem based on the history and clinical signs or on a definitive diagnosis in herdmates of affected animals. If a diagnosis of PEM is made, either presumptive or definitive, attention should be focused on identifying the likely causes so that exposure of herdmates to etiologic agents can be mitigated or eliminated. The investigation may proceed at the animal, herd, and environmental level to identify evidence supportive of sulfide toxicity, thiamine deficiency, lead toxicity, or water deprivation—salt toxicosis.

Sulfide concentrations in the ruminal fluid and gas cap in experimentally induced sulfur-associated PEM have been shown to be high.[1082,1083] However, unpublished data supported a finding of a decrease in gas cap sulfide concentrations in naturally developing PEM associated with increased sulfur consumption.[1084] This probably is caused by the rapid metabolism of sulfate to sulfide in the rumen and resultant absorption or eructation of hydrogen sulfide (H_2S). Animals with naturally developing PEM are likely to have been anorectic for some time, resulting in a decrease in oxidized and reduced forms of ruminal sulfur.

Estimation of the rumen gas cap H_2S concentration in clinically healthy penmates of affected cattle is an effective chute-side diagnostic procedure that can indicate excessive sulfur consumption.[1071] This method provides real-time results that may aid direction of further animal and environmental investigations. In short, an area in the left paralumbar fossa is prepared for ruminocentesis. An 18-gauge, 3½-inch spinal needle is inserted through the body wall and into the rumen gas cap. A modified gas sampler is attached to the spinal needle by means of an extension set, and a known amount of gas is drawn through an H_2S detector tube.[1083] It is important to adjust the values to account for any dead space of the sampling instrument, such as the extension set and other modifications. H_2S concentrations greater than 1000 ppm are indicative of excessive sulfur consumption.[1085]

Appropriate blood samples may be analyzed for lead concentration and possibly estimation of thiamine status. Thiamine status generally is evaluated using one of several available methods, including determining the total blood thiamine concentration using a thiamine-dependent *Lactobacillus* bioassay.[1086] The erythrocyte thiamine pyrophosphate concentration may be measured by high-performance liquid chromatography (HPLC).[1087] The value of estimating all phosphorylation forms of thiamine (free, diphosphate, and triphosphate) is questionable. Table 35-9 shows the reference ranges for the total thiamine concentration in normal and affected cattle.

Another method of evaluating thiamine status is determining erythrocyte transketolase activity. This is a sensitive and specific measurement of active thiamine status.[1088] Transketolase catalyzes the reaction

between xylulose-5-P and ribose-5-P to form sedoheptulose-7-P and 3-phosphoglyceraldehyde in the pentose phosphate pathway. Normal mean transketolase activity has been reported to range from 0.301 to 2.9 mmol pentose/hr/10^9 RBCs (mean, 0.782). Transketolase assays often are reported as the mean thiamine pyrophosphate effect (Table 35-10). This test compares the specific activity in the active (holoenzyme) and inactive (apoenzyme) forms with the activity of the two forms after addition of thiamine to the homogenates. A large increase in specific transketolase activity after addition of the thiamine pyrophosphate suggests thiamine deficiency. Theoretically, in animals with thiamine-associated PEM, the concentration of holoenzyme is decreased, and that of the apoenzyme is increased. Thiaminase may be detected in the rumen and feces of affected animals, but the value of this assay is questionable.[1072,1087,1089,1090] If thiamine deficiency is identified in an affected animal, caution should be used in interpreting the results because a period of anorexia may result in a decrease in ruminal de novo synthesis;[1092,1091] thus, affected animals may have a thiamine deficiency that develops secondary to PEM.

Changes in CSF of affected animals usually are vague. They include mild pleocytosis (5 to 50 WBCs/dL) with vacuolation and increased protein concentrations (>50 mg/dL).[1072,1093]

Electrophysiologic studies of affected animals show a normal latency and decreased amplitude of the late peaks of the visual-evoked potentials. These changes reflect a decreased population of neurons capable of responding to the photic stimulation.[1094] Electroencephalographic (EEG) changes in some animals include constant high amplitude (50 to 60 mV) and slow activity (1 to 4 Hz). Another change is diffuse lowered activity, which is consistent with diffuse necrosis.[1095]

Table 35-9 Mean Concentration of Thiamine in Tissues*: 95% Confidence Intervals in Clinically Normal Cattle and Sheep and in Patients with Polioencephalomalacia

Tissue	Species	Normal	Polioencephalomalacia
Liver, wet	Cattle	2.81 ± 0.515	0.613 ± 0.102

Environmental investigations should include evaluation of all practical feed and water sources for sulfur concentrations or the possibility of lead contamination. The diet should also be checked for molasses and urea content.

35.2.33.4 Pathogenesis

The fundamental lesion with PEM appears to be neuronal edema with secondary compartment syndrome. In most cases the edema is postulated to result from adenosine triphosphate (ATP) depletion and insufficient function of the sodium-potassium pump. With salt intoxication, aberrant accumulation of intraneuronal osmolar substances, followed by mass movement of water into neurons, offers a different pathway to cerebral edema. In either case, the bony calvarium limits expansion, and neuronal swelling leads to pressure necrosis. Additional neuronal dysfunction independent of edema and compartment syndrome cannot be ruled out.

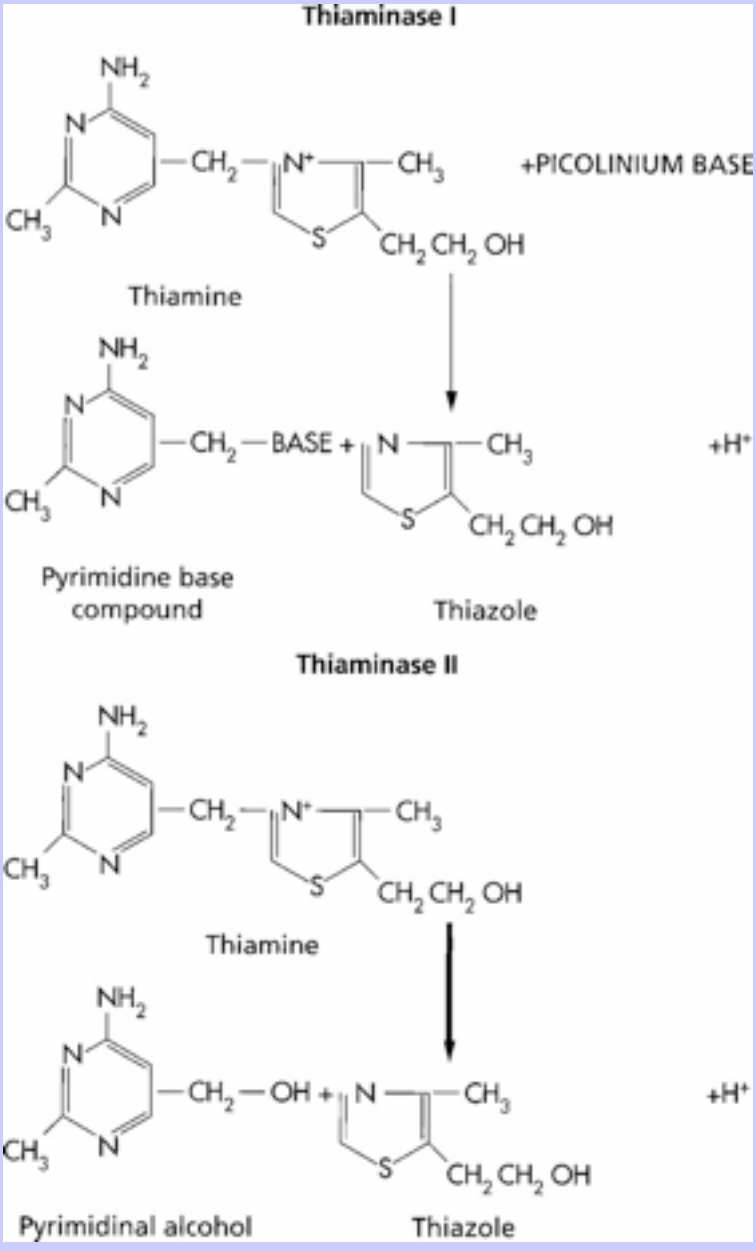
The brain is susceptible to PEM because of its high energy and oxygen requirements. Brain tissue is only about 2% of body weight but accounts for 20% to 30% of body glucose utilization and 20% of oxygen utilization in adults.[1096] More than 85% of glucose used by the brain is energy substrate, and the blood-brain barrier prohibits the switching to many alternate energy substrates. Compared with liver or muscle, the brain has relatively small glycogen stores, only about a 10-minute supply. It is entirely dependent on circulating oxygen, and under normal conditions, the extracellular fluid contains approximately 100 times as much glucose as the oxygen required for complete aerobic glycolysis. Thus, oxygen delivery or utilization is much more rate limiting for ATP production under most circumstances than glucose availability,[1097] and factors that inhibit oxygen utilization (e.g., H_2S, lead) could have profound effects on neuronal ATP production.

One intriguing but controversial theory on cerebral energy metabolism could further explain the high neuronal susceptibility to ATP depletion. By this theory, glucose is reduced anaerobically to lactate in astrocytes.[1098] This lactate diffuses into neurons, which are then absolutely dependent on aerobic glycolysis for ATP production. Even if this theory is false, it is unlikely that anaerobic glycolysis alone could meet neuronal ATP needs.

Much of the early work on PEM focused on the importance of thiamine (vitamin B_1, thiamin, aneurin). In adult ruminants, thiamine is produced by rumen microbes at a rate that is marginally faster than the rate of consumption; very little is stored.[1099] Preruminants depend on dietary thiamine. Thiamine compounds play several important roles in the glycolytic pathways. Thiamine pyrophosphate (thiamine diphosphate) is an important coenzyme for transketolase, the rate-limiting enzyme in the hexose monophosphate pathway (pentose phosphate shunt) of glycolysis, and the α-ketoacid dehydrogenases of the Krebs cycle. The role of thiamine in the hexose monophosphate pathway was long thought to be key in the development of PEM, but this pathway actually accounts for less than 3% of cerebral glycolysis.[1100] It is unlikely that impairment of this pathway alone could lead to such severe disease. However, decreased function of the Krebs acid cycle through inactivity of the α-ketoacid dehydrogenases could probably cause the necessary reduction in ATP production. Thiamine triphosphate may also play a role in neuronal function independent of its enzymatic function.

The dependence of ruminants on microbial thiamine production has lead to investigation of factors that might decrease production, absorption, or function. The mechanisms proposed include ruminal production of bacterial thiaminases, production or ingestion of inactive thiamine analogs, ingestion of preformed plant thiaminases, decreased intake of preformed thiamine by preruminants, impaired absorption or phosphorylation of thiamine by rumen bacteria, increased fecal excretion of thiamine, and decreased ruminal production of thiamine diphosphate. The most frequently reported inactive thiamine analog is amprolium.[1074–1076] Two types of bacterial thiaminases have been described. Thiaminase I, which is produced by *Bacillus thiaminolyticus* or *Clostridium sporogenes,*[1101] catalyzes the cleavage of thiamine at the methylene bridge between the pyrimidinyl and the thiazole ring. A basic cosubstrate is required to combine with the pyrimidinyl derivative to form a new compound[1102] (Fig. 35-13). Many common feedlot medications, including benzimidazoles, levamisole, and promazines, appear to be able to serve as this cosubstrate.

Fig. 35-13 Enzymatic cleavage of thiamine by thiaminase I and II. Thiaminase I attaches a picolinium base to the pyrimidine ring structure, whereas thiaminase II catalyzes the hydrolysis of thiamine at the methylene bridge. (From Edwin EE, Jackman R: A rapid radioactive method for determination of thiaminase activity and its use in the diagnosis of cerebrocortical necrosis in sheep and cattle, *J Sci Food Agric* 25:357, 1974.)



Several plants also appear to make a thiaminase similar to thiaminase I. These include bracken fern *(Pteridium aquilinum)*[1103,1104] horsetail *(Equisetum arvense),*[1104] and Nardoo fern *(Marsilea drummondii)*.[1105] Of these, only the Australian Nardoo fern has been strongly linked to outbreaks of PEM. Thiaminase II is produced by *Bacillus aneurinolyticus,* which proliferates in response to excessive grain intake.[1106] The enzyme catalyzes the hydrolysis of the methylene bridge between the two ring structures of the thiamine molecule. The specific relationship of this thiaminase to the clinical syndrome of PEM as seen in the field is unclear.

Complete correlation has not been established among production of ruminal and fecal thiaminase, tissue and plasma concentration of thiamine, and development of clinical encephalopathy.[1089,1107] Some affected animals may show normal amounts of thiamine in the plasma but have greatly decreased levels in the erythrocytes and other tissues, supporting the diversity of causes of PEM.[1108]

Dietary sulfur and sulfates are an important factor in the development of many cases of ruminant PEM. Beef cattle require 0.15% to 0.20% sulfur on a dry matter basis.[1109] Sources of sulfur include elemental sulfur,[1067] feed additives such as gypsum and ammonium sulfate,[1068,1110] feedstuffs such as corn-processing by-products,[1109] cruciferous crops,[1111,1112] molasses,[1077] and fertilizers. Water can be an important contributor to sulfur intake, usually in the form of sulfates.[1070,1113,1114]

There are two primary metabolic pathways of sulfur in the rumen.[1114–1119] The *assimilatory pathway* involves reduction of sulfate to sulfides and incorporation into sulfur-containing organic compounds such as cysteine and methionine.[1117] These are ultimately incorporated into microbial crude protein. The *dissimilatory pathway* is an energy-producing pathway in which microorganisms use sulfate as a terminal electron acceptor, similar to how mammals use oxygen.[1120] The end product is liberated sulfide ion. At a ruminal pH of 5.2, 97.2% of sulfide ions are in the form of H_2S and move freely to the rumen gas cap.[1116,1121] H_2S is readily absorbed and transported to the liver and oxidized to sulfate.[1121,1122] Some H_2S may be lost through eructation,[1082,1121] but the significance of this route has been questioned.[1123] Excess sulfur is excreted in the urine and large intestine[1124,1125] or recycled to the rumen.[1126,1127] A period of adaptation is required for maximum H_2S production after exposure to sulfur.[1118,1124,1127–1129]

Because sulfur and sulfate demonstrate low cellular toxicity, it is unlikely that sulfur-associated PEM results from a sulfate or sulfur toxicity. However, sulfides are highly toxic.[1130–1132] Sulfur-associated PEM is more likely to occur secondary to a sulfide toxicity.[1069,1071,1082]

It has been proposed that the pathogenesis of sulfur-induced PEM involves inhibition of cytochrome-*c* oxidase, an enzyme in the electron transport chain; this chain is important for regenerating the intermediaries of aerobic glycolysis and the final round of ATP production. With oxygen availability already limiting aerobic glycolysis in the brain, inhibiting the electron transport chain could have a profound effect on neuronal ATP production.

For highly toxic sulfide to reach the brain, it must escape hepatic oxidation. This might be achieved by two mechanisms. A surge in ruminal sulfide generation usually follows a period of adaptation to high-sulfur diets. This may overwhelm the hepatic detoxification capacity. As an alternative possibility, cattle inhale the majority of eructated ruminal gas.[1133] These inhaled gases can contain high amounts of H_2S, and if absorbed

via the pulmonary route, the H_2S would completely bypass the hepatic circulation. However, this concept has been questioned.[1134]

In feedlot cattle, a summer peak in PEM cases was associated with consumption of water containing 2500 mg/L of sulfate.[1070] The total sulfur intake of these steers was estimated to be 0.6% on a dry matter basis during the hottest days of the year. Most PEM cases occurred between 15 and 35 days after arrival in this feedlot. In another investigation, 11% of weaners consuming a diet containing 0.9% sulfur on a dry matter basis developed clinical manifestations of PEM.[1071] Lesions were confirmed in one steer that died. Addition of gypsum (calcium sulfate) to feeder steer rations at a final concentration more than 2% organic sulfate results in a significantly greater risk of developing PEM. The addition of sodium sulfate (0.6% to 0.8%) to diets may induce PEM within 11 days.[1082,1128,1135,1136] High sulfur concentrations in well water in combination with accumulation in forage has been traced to an outbreak of PEM in Canada.[1071] One survey described an outbreak of cerebrocortical necrosis in cattle eating diets containing 7200 mg/kg of sodium sulfate.[1114]

1024

1025

The recommended maximum tolerance level of sulfur is 0.4% of dry matter intake.[1109] Other effects of excessive sulfur intake are decreases in feed intake and weight gains. Accurate diagnosis of sulfur toxicity requires measurement of sulfur in all food and water sources. Sulfur from water must be included when calculating total sulfur intake. One third of the molecular weight of sulfate is sulfur. Therefore, if an animal drinks 30 L of water a day containing 2000 mg/L of sulfate, this contributes 60,000 mg of sulfate, or 20 g of sulfur. Furthermore, if this animal consumes an average of 10 kg of dry matter daily at 0.15% sulfur, the feed or forage contributes 15 g of sulfur, making the total sulfur intake 35 g, or 0.35% on a dry matter basis. Water therefore may be a substantial source of sulfur.

Some have suggested that sulfides result in thiamine destruction, thereby directly implicating a thiamine deficiency in the pathogenesis of sulfur-associated PEM. Rumen thiamine production was slightly reduced by the inclusion of excessive sulfur in the ration.[1137] However, the authors deemed the reduction clinically insignificant. Apparently, sulfur-associated PEM occurs independent of thiamine status.

PEM induced by feeding of molasses and urea is thought to be related to the high sulfur content of the molasses and to the depletion of propionate and other glucogenic precursors induced by the foodstuff.[1077] It is not considered to be caused by an underlying thiamine destruction. The tissue thiamine concentrations of animals with molasses-related PEM are normal,[1138] and signs are preventable by concomitant feeding of glycerol, which is converted to glucose in the rumen. Outbreaks of PEM in range cattle have been associated with ingestion of the plant *Kochia scoparia*.[1139,1140] The pathogenesis of this condition is unknown; however, some have suggested that the plant has the capacity to accumulate sulfur in the forage.[1114]

Some cases of PEM cannot be linked to either problems with thiamine or sulfur toxicosis. Other compounds, such as lead, affect electron transport in a manner similar to sulfides and therefore also impair ATP production. Water intoxication creates a similar histologic lesion, but the pathogenesis of edema relates more to the generation of osmotic compounds and fluid shifts with rapid fluctuations of blood and neuronal osmolality.

35.2.33.5

Epidemiology

PEM has a worldwide distribution. The condition is seen both in individuals and as herd outbreaks. In one instance, approximately 2000 of 2200 sheep grazing were clinically affected with PEM.[1067] No predilection by gender or breed is seen, although anecdotal reports suggest that heifers are less likely to develop PEM than steers in a feedlot environment. The condition affects cattle, sheep, goats, deer, camels, and camelids.[1068,1074,1141–1144] Although PEM is seen predominantly in animals that eat a high-concentrate supplement, the condition also can occur in unsupplemented animals on pasture. The inciting cause of PEM can be identified in some cases.

One report from the United States indicated a predominance of cases in the summer in range cattle.[1064] The age range for susceptibility to PEM has been reported as 3 weeks to 5 years in sheep, 3 weeks to 8 years in cattle, and 2 months to 2½ years in goats. The peak age of incidence is 18 months or younger in cattle and sheep, but this depends on the production system.[1064,1071,1145] The incidence of PEM has been reported as high as 90% in some sheep flocks, with mortality of 1% to 10%.[1067] The incidence of PEM is high in sheep exported by sea from Australia to the Middle East. In these cases the underlying disturbance was thought to be associated with a thiamine deficiency caused by a lack of rumen synthesis secondary to the shipboard conditions.[1146]

35.2.33.6

Necropsy Findings

In cases of sulfur-associated PEM, rumen contents may have an odor of H_2S. In other cases there may be evidence of grain overload, coccidiosis, or respiratory disease. Some of these lesions relate to management conditions, but may also relate directly or indirectly to PEM. The macroscopic pathologic brain lesions of PEM include cortical swelling, softening, flattening, and yellowish discoloration of the gyri. Necrotic areas of the cerebral cortex autofluoresce under ultraviolet light (365 nm).[1147,1148] Severe cases show herniation of the cerebellum through the foramen magnum or the occipital cortex under the tentorium cerebelli. Animals necropsied months after recovery may show cerebral atrophy and submeningeal cortical cysts. The major microscopic lesion is a diffuse laminar necrosis. Other changes include intracellular and intercellular edema, neuronal necrosis, gliosis, and neuronophagia.[1066,1080]

35.2.33.7

Treatment and Prognosis

Regardless of the underlying cause, animals with the subacute form of PEM often respond favorably to parenteral administration of thiamine hydrochloride. These animals may remain blind and may have depressed sensorium for weeks or months.[1149] Thiamine should be administered at 10 to 20 mg/kg IM or subcutaneously (SC) three times daily. In severe cases, IV administration of the first dose might be warranted. If given IV, thiamine should be diluted in 5% dextrose or other isotonic fluid and administered slowly to avoid adverse reactions. If no improvement occurs initially, the treatment should be continued for at least 3 days. In some patients, recovery may take as long as 7 days, but most patients show improvement by 24 hours. A single administration of sodium dexamethasone at 1 to 2 mg/kg IM or IV or 1 g/kg of mannitol in a 20% solution IV may be beneficial in reducing cerebral edema. Anecdotal reports indicate that feedlot animals that have recovered from PEM are at increased risk of respiratory disease; therefore,

prophylactic antimicrobial administration may be indicated. Convulsions may be controlled with phenobarbital, pentobarbital, or diazepam. Specific dosing regimens are listed in Tables 35-7 and 35-8.

Animals with the acute form of PEM usually have more severe cortical and deep gray matter lesions than animals with the subacute form.[1071] These animals generally do not respond to therapeutic regimens. Ruminants with PEM secondary to the molasses-urea diet do not appear to respond to treatment with thiamine. They may respond more favorably to parenteral administration of glucose or enteral or parenteral administration of a glucose precursor.

35.2.33.8 Prevention and Control

Thiamine supplementation may not prevent outbreaks of PEM. Ultimately, the best way to prevent outbreaks is to manage the dietary intakes of susceptible animals appropriately. Ruminants should be allowed an adequate period of adaptation to high-concentrate rations. All feedstuffs and water sources should be carefully analyzed on a routine basis with an estimate of total sulfur intake. If excess sulfur consumption is a factor, steps should be taken to remove sources such as high-sulfur hay, ammonium sulfate, and molasses. If the excess sulfur intake is unavoidable, steps can be taken to limit its effects. Older members of the cow herd could be used to graze the high-sulfur pastures, and younger, more susceptible animals could be kept to lower-sulfur pastures or given hay supplementation. Personnel should be trained so that animals with PEM can be identified early in the disease and treated appropriately.

1025

1026

Thiamine may be supplemented (3 to 10 mg/kg of feed) in rations in which the concentrate/fiber ratio is high, but this has little or no effect in preventing PEM. Other recommendations for preventing PEM include addition of brewer's yeast to the ration and gradual adaptation of ruminants (at least 2 weeks) to high-concentrate diets. If present as a feed-limiting additive, gypsum should be removed from the diet. Elimination of supplementation and rotation of pastures have been sufficient for controlling some outbreaks.[1145] Supplementation with cobalt in trace-mineral salt mixes may be necessary in deficient areas.

35.2.34 THIAMINE DEFICIENCY OF HORSES

Horses may develop thiamine deficiency when fed diets that contain thiaminases. Common sources of thiaminases are bracken fern *(Pteridium aquilinum),* horsetails *(Equisetum arvense),* and amprolium (400 to 800 mg/kg). The clinical signs of thiamine deficiency are ataxia, conscious proprioceptive deficits, heart block, bradycardia, blindness, weight loss, dysuria, hypothermia of the extremities, and periodic muscular fasciculations. Terminally, affected horses develop convulsions. Electrolyte changes include hyperkalemia, hyperphosphatemia, hyperglycemia, and decreased glucose tolerance. Parenteral thiamine is effective treatment.[1150,1151]

35.2.35 SALT POISONING

35.2.35.1 Definition and Etiology

Salt poisoning is a common CNS disease of livestock. Salt-rich solutions ingested over time can cause production-related losses and even death. Ingestion of water containing more than 7000 mg/L of total dissolved salts is likely to result in acute salt poisoning.[1152,1153] Water that contains less than 3000 mg/L of total dissolved salts is considered safe for consumption. Salt poisoning can be associated with water

deprivation.[1152,1154,1155] Provided that access to free water is constantly available, animals may tolerate as much as 13% dietary salt intake.[1156] The total dietary salt concentration should never exceed 4%.

The acute toxic dose of oral sodium chloride (NaCl) for cattle and horses has been reported as approximately 2.2 g/kg body weight and for sheep about 6 g/kg.[1156] With water restriction, the toxic dose of salt is considerably less, and poisonings have resulted from ingestion of 0.9% NaCl in water-restricted cattle.[1157] Chronic toxicity can occur at lower dietary salt levels than acute toxicity. Ingestion of water with salt concentrations above 1% uniformly results in toxicosis if no other source of ion-free water is provided.[1158,1159]

Ingestion of water containing 0.7% salt lowers the fertility of females,[1159] and water containing 0.25% salt suppresses milk production in cattle.[1160] Dairy calves have been poisoned by daily feeding of 4 L of milk replacer containing 2.6% NaCl.[1161] Animals are most susceptible to salt poisoning during the summer because of the increased insensitive loss of water at that time. Salt poisoning in ruminants is most frequently a syndrome of "water intoxication": a period of restricted access to low-salt water, followed by unrestricted access to water.[1152,1154,1155]

35.2.35.2

Clinical Signs

Rapid ingestion of large amounts of salt causes gastrointestinal and neurologic signs.[1158,1161–1166] These include mucohemorrhagic diarrhea and colic, head-neck extension ("star gazing"), blindness, aggressiveness, hyperexcitability, psychomotor seizures (paddling and loss of consciousness), vocalization, ataxia, proprioceptive deficits, head pressing, constant chewing movements, nystagmus, muscle twitching, and coma. Death occurs as a result of respiratory failure. Before the onset of neurologic signs, cattle with chronic salt toxicosis may appear to be depressed and dehydrated. Table 35-11 summarizes the spectrum of clinical effects associated with different levels of salt intake.

Excessive salt intake also may interfere with productivity in the absence of acute neurologic signs. In one study, cattle were given either tap water (196 ppm of dissolved salts) or saline (2500 ppm NaCl), and their milk production was measured.[1160] Cows given tap water had a greater fluid intake and a significantly greater lactational persistence and daily milk production than did cows given saline. The serum concentrations of sodium and potassium were normal in the animals fed saline.

The clinical diagnosis of salt poisoning depends on the demonstration of exposure to toxic concentrations (>7000 ppm or 0.7% of sodium), the presence of water deprivation, or the determination of serum or cerebrospinal fluid (CSF) sodium concentrations greater than 160 mEq/L. CSF/serum sodium ratios greater than 1 also suggest salt poisoning. The serum sodium concentration may vary, depending on whether the patient had recently been given ion-free water before measurement. Some animals with acute neurologic lesions may be normonatremic if they have recently drunk to repletion with ion-free water, whereas others that have not had ion-free water may be hypernatremic. The CSF sodium concentration in salt-poisoned animals is consistently elevated and may exceed 200 mEq/L.[1162] Ruminal sodium concentrations above 0.36% to 0.5% or brain sodium concentrations above 150 mEq/g or 1800 ppm[1167] also suggest salt poisoning in cattle.[1162,1163,1168] Rapid intake of low-sodium water during the rehydration phase of the disease may cause intravascular hemolysis with resultant hemoglobinuria; such findings raise the index of suspicion of salt poisoning.[1153]

Table 35-11 Effects of Different Salt Concentrations in Drinking Water on Performance in Cattle

Salt Concentration (mg/L or ppm)	Clinical Effect
<1000	No effect
1000–3000	Temporary diarrhea; reduced milk production
3000–5000	May reduce milk production and feed intake; may produce reproductive failures (failure to conceive)
5000–7000	Conception failures (abortion, infertility), reduced appetite
7000	Unsafe, especially in hot weather; may produce encephalopathic signs, abdominal pain, mucoid diarrhea, thirst, salivation, polyuria, central nervous system signs; include knuckling, blindness, convulsions, coma, and abdominal pain

From McCoy CP, Edwards WC: Sodium ion poisoning in livestock from oilfield wastes, *Bovine Pract* 15:152, 1980.

1026

1027

The concentration of acetylcholinesterase in plasma and RBCs is decreased in animals that have been ingesting excessive salt (>0.49% of diet).[1169] The decrease is first seen after 4 months of continuous ingestion of the high-salt diet.

35.2.35.3

Pathophysiology

The pathogenesis of salt poisoning involves the deposition of sodium ions in the CNS parenchyma and the CSF, which occurs either acutely from ingestion of a large quantity of salt or chronically after long periods of reduced water consumption. The ionic sodium accumulates in the CSF and neurons by passive diffusion. The resulting hyperosmolality reduces energy-dependent sodium transport mechanisms and the anaerobic glycolytic pathways.[1170] These mechanisms normally provide energy by which the sodium ion is removed from the cell cytoplasm.[1165] The thirst receptors are triggered in response to the hyperosmolality. The animal is permitted to drink ion-free water to repletion, and the fluid is absorbed from the gastrointestinal tract, resulting in expansion of the extracellular fluid and a return to normal plasma osmolality. Water then diffuses from the blood into the relatively hyperosmolar CSF and neurons, resulting in CNS edema, increased intracranial pressure, and acute encephalopathy. If the patient has had sudden access to a large quantity of salt, the hyperosmolality in the intestine results in saline catharsis and diarrhea.

35.2.35.4

Epidemiology

Animals are tolerant of high dietary salt levels if they have concomitant access to fresh drinking water. Feedstuffs that are common sources of excessive salt include whey, saline-preserved fish or fish meals, bakery by-products, and certain milk replacers.[1171] Confined calves may be poisoned by improperly formulated milk replacers or oral electrolyte replacements.[1162,1171] Cattle eagerly ingest large amounts of oil well sludge, which is a potential source of salt for cattle in the western and southwestern United States.[1166,1172,1173] Brine is used extensively as a flush during the drilling of oil wells. Effluents from drilling rigs

may contain as much as 100,000 ppm of salt. The effluents are also contaminated by heavy metals and magnesium salts, which complicate the clinical syndrome of salt poisoning. Concurrent neurologic disease may predispose animals to reduced water intake, as occurred in a group of goats with locoweed (*Oxytropis* species) poisoning who became water deprived because of reluctance to move to a water source. They developed clinical and pathologic evidence of salt poisoning when moved subsequently to an area where water was easily available.[1154] Salt poisoning caused by water restriction may occur either inadvertently from freezing of water sources in northern climates or from intentional water restriction of veal calves.[1162] Ingestion of brackish or tidal water is a cause of salt poisoning in cattle pastured on the coastal regions of the world.

35.2.35.5

Necropsy Findings

The pathologic changes of salt poisoning include cerebral edema and softening and flattening of the cortical gyri. Microscopic lesions include laminar cortical necrosis, poliomalacia, and occasionally, meningeal or perivascular infiltration of eosinophils. Perivascular infiltration of eosinophils is not as reliable an indicator of salt poisoning in ruminants as in pigs because most affected ruminants show perivascular cuffing of mononuclear cells.

35.2.35.6

Treatment

Treatment of animals affected by salt poisoning is difficult. Many animals die even after intensive medical treatment. Prognosis depends on severity of clinical signs at the start of treatment: animals that already have significant cerebral edema have a guarded prognosis. Therapy should be aimed at limiting the ingestion of nonionic water and attempting to remove intracellular solutes slowly from the brain while simultaneously controlling cerebral edema and attendant CNS signs. To prevent brain swelling and herniation of the brain through the foramen magnum or the tentorium cerebelli, slow reduction of the CSF and plasma sodium is imperative. Slow intravenous (IV) administration of normal or hypertonic saline is the mainstay of treatment.

Adult cattle should receive normal or hypertonic saline intravenously (IV) at maintenance rate (7% body weight in adult cattle, 10% in neonates).[1153] Slight underestimation of fluids is preferable to excess fluid administration. Serum sodium should be monitored regularly and correction effected over 24 hours or longer. Oral fluids can be introduced gradually toward the end of the first day of treatment; salt should initially be added to oral fluids to make them isotonic to blood. When IV replacement is not feasible, isotonic to hypertonic oral fluids should be administered at a maintenance level divided into four to six feedings daily. Access to low-salt water is gradually allowed after 3 to 4 days. Any worsening of clinical signs is an indication to increase the salt level in fluids and may require IV mannitol (0.5 to 2.0 mg/kg as a 20% solution) or oral glycerin (1 mL/kg diluted 50:50 with water) to reduce cerebral edema.[1153]

In calves, treatment can be accomplished by administration of hypertonic saline concomitantly with feeding of 2 to 4 L of fresh milk daily. First, the plasma sodium concentration is measured, and the calf then is given 1 to 2 L of a hypertonic saline solution IV. The molar strength of the sodium ion in the IV fluid should be equal to or slightly greater than that of the plasma. If the hypotonicity of the whole milk is not counterbalanced by treatment with hypertonic saline, the CNS will rapidly expand as a result of absorption of free water. The plasma electrolyte concentration is measured twice daily. If the plasma sodium concentration declines too rapidly, 1 L of hypertonic saline solution is infused over several hours. The concentration of sodium in this fluid should be greater than the most recent plasma sodium measurement and less than the beginning plasma sodium concentration. If the calf develops nervous twitching, salivation, head-neck

extension, stiff forelimbs, or convulsions, 0.5 to 1 g/kg of mannitol is immediately infused IV. A blood administration set is used to filter insoluble mannitol crystals. The calf should have no access to fresh water.

The use of solutions containing 5% glucose is dangerous and probably contraindicated because this represents ion-free extracellular fluid, which can exacerbate brain edema. Administration of corticosteroids (dexamethasone, 0.4 to 0.8 mg/kg by slow IV injection twice daily for 2 to 3 days) may be helpful in animals with acute cerebral edema. However, potential benefits should be weighed against the possibility of inducing extrarenal sodium retention. If the neurologic signs diminish and the plasma sodium level returns to normal, the animal may be given fresh ion-free drinking water. Thiamine (10 mg/kg by slow IV injection) may be a useful adjunctive therapy.

35.2.35.7 Control

Cattle should be fenced away from polluted ponds and oil wells. Cattle on coastal pastures should have access to fresh well water. The total daily dietary salt intake should not exceed 4% of dry matter intake. Drinking water must contain less than 7000 ppm of sodium unless the dietary sodium load is reduced correspondingly. Oral rehydrating fluids for calves should be dissolved in strict accordance with the manufacturer's recommendations and should not be administered for longer than 3 consecutive days.

1027

1028

35.2.36 VITAMIN A DEFICIENCY

35.2.36.1 Definition and Etiology

Vitamin A (retinol) is found in green plants and can be synthesized by the small intestinal mucosal cells from plant carotenoid precursors. Precursors of vitamin A are usually fed in cattle rations as β-carotene or as retinoids (retinyl palmitate or acetate). Carotenoid in forage is converted to retinol in the liver and gut. Vitamin A deficiency occurs primarily in growing ruminants in feedlots. Deficiency develops under these conditions because the growing animal has a higher requirement for the vitamin, and feedlot-reared animals may have limited access to succulent plants. The vitamin is labile in foodstuffs and is essentially depleted after several years of storage. Diets that are naturally low in vitamin A include cereal grains, beet pulp, and cottonseed hulls. Conditions in which the immune system is challenged, as when exposure to pathogens is high, also increase the requirement for vitamin A.

The clinical signs of vitamin A deficiency in cattle are related to increased intracranial pressure and ill-thrift caused by secondary infections. Signs include intermittent convulsions, depression, and blindness. The usual dietary or management conditions that favor the vitamin deficiency include grazing on dry pastures or cereal grains other than corn, exclusive feeding of cereal grains that have been stored at high temperature and humidity, or prolonged feeding of mineral oil as a preventive for frothy bloat.

35.2.36.2 Clinical Signs

The neurologic signs of vitamin A—depleted animals are age dependent. Signs in deficient calves include anorexia, ill-thrift, blindness, diarrhea, and pneumonia. The syndrome in adults is characterized by “star-gazing” posture, blindness, diarrhea, anasarca, nystagmus, strabismus, exophthalmos, loss of pupillary light reflexes, and intermittent tonic-clonic convulsions. The seizures last for only a few minutes and are followed by partial recovery.[1174–1176] Animals may die during seizures. Stimulation of the animals frequently

precipitates seizures.[1177,1178] Death often is preceded by hyperesthesia and coma.[1174,1175,1179] Inadequate vitamin A supplementation of calves is associated with unthriftiness, intermittent fevers, and a higher incidence of diarrhea.[1180] Vitamin A—deficient adults appear to be in good body condition unless parasitism or some other nutritional deficiency is superimposed on the low vitamin A intake.[1174,1181] Secondary factors that can influence the appearance of the animals include concomitant nutritional deficiencies, parasitism, and pneumonia.

The ocular changes of vitamin A deficiency are characteristic. The pupils become dilated and unresponsive. As papilledema develops, the optic disc becomes pale and its borders become indistinct, particularly in the upper quadrants,[1174,1176,1182] giving the appearance of an inverted heart. The swollen disc may cast a shadow on the adjacent retina. The color of the disc becomes faded. In advanced cases the disc may become atrophic and appear dull, gray, flattened, and smaller than normal. The retinal blood vessels become tortuous or appear to be occluded as they course over the disc. Retinal detachment and subretinal hemorrhages are possible.[1174] Corneal changes are an uncommon clinical finding.[1174,1175]

Reproductive disturbances can occur, including malformed fetuses, abortions, loss of libido, testicular degeneration, and decreased sperm counts. Calves born to vitamin A—deficient dams are blind, have domed foreheads and thickened carpal joints, and are weak at birth.[1183]

Vitamin A deficiency can be clinically differentiated from polioencephalomalacia (PEM) and salt poisoning by comparing the menace response with the pupillary light reflex. Calves with lead poisoning and PEM generally have intact pupillary light reflexes because of the proper functioning of the mesencephalon and optic nerves, whereas vitamin A—deficient cattle have absent pupillary light responses because of retinal degeneration and constriction of cranial nerve II at the level of the optic foramen.

35.2.36.3 Clinical Pathology

Assay of vitamin A and carotene concentrations in the plasma and feed is the most direct method of diagnosing the dietary deficiency. The concentration of plasma vitamin A and β-carotene in normal animals ranges from 25 to 85 μg/dL and 150 and 397 μg/dL, respectively.[1175] Plasma concentrations of vitamin A—deficient and β-carotene—deficient animals usually are less than 7 and 70 μg/dL, respectively. Papilledema first occurs when plasma concentrations of the vitamin fall below 18 μg/dL.[1184] Ataxia and blindness occur when the serum vitamin A concentration ranges from 4.87 to 8.88 μg/dL.[1177] The hepatic concentration of vitamin A and carotene in normal calves ranges from 60 to 200 and from 4 to 800 μg/g of tissue, respectively. In deficient calves the hepatic concentrations of the vitamin A and carotene nutrients range from 2 to 14 and from 0.5 to 32 μg/g, respectively.[1181,1184] There are no consistent changes in the blood chemistry analysis or the hemogram of deficient animals. Increased CSF pressure (>200 mm Hg) may occur; however, standardization of the measurement for all forms of anesthesia and methods of measurement is difficult.[1185] Changes in the CSF of vitamin A—deficient animals include a mononuclear cell pleocytosis (40 to 50 nucleated cells/dL) and an increased protein concentration (140 mg/dL).[1186]

35.2.36.4 Pathophysiology

Vitamin A is responsible for the regeneration of rhodopsin in the retina and the maintenance of tissue integrity. The vitamin has effects on osteoblasts and osteoclasts, epithelial tissues, the choroid plexus, and

reproductive tissues. The arachnoid villi and the retina are most sensitive to a deficiency of the vitamin. Vitamin A deficiency causes a thickening of the dura mater, resulting in diminished CSF absorption from the arachnoid granulations and the nerve rootlets. Narrowing of all the bony foramina of the skull occurs in immature animals, although bone remodeling does not occur in adults. The combined effects cause an increase in CSF pressure.[1181] In severe cases the brain may herniate through the foramen magnum. Closure of the optic foramen may lead to transection of the optic nerve. The high CSF pressure is transmitted into the optic nerves and results in papilledema.

Three causes of blindness have been associated with vitamin A deficiency. Nyctalopia is presumably caused by the decreased formation of vitamin A aldehyde in the regeneration of the visual pigment rhodopsin; this type of blindness usually is reversible. Degenerative changes in the outer retinal layers also cause blindness; this is reversible if treated in the early stages. The third cause is associated with stenosis of the optic foramen and compression of the optic nerve; this condition is irreversible.[1187] An experimental study has shown that humoral immune function also is impaired in sheep with vitamin A deficiency. The pathogenesis of this condition is unclear.[1188]

35.2.36.5

Epidemiology

The vitamin A requirement of all species ranges from 40 to 110 IU/kg daily.[1189–1191] The minimum recommended daily dose of vitamin A for growing calves up to 1 year of age, for pregnant sheep, and for growing horses is 40 IU/kg. Pregnant cattle and pregnant or lactating horses require 40 to 50 IU (13.76 to 17.2 µg/kg) of vitamin A daily.[1189] Lactating cattle require 80 IU (27.5 µg/kg) of vitamin A daily. Horses are susceptible to vitamin A deficiency, but the condition is rarely seen in that species. This is thought to be the result of differing conditions of management rather than an inherent resistance to the deficiency. The daily dietary requirement for carotene is 0.12 mg/kg.[1189] Pasture forage, silage, and properly cured hay (<1 year old) contain large amounts of carotene. Common constituents that have low concentrations of vitamin A are sorghum, brewer's grain, and wheat straw.

1028 1029

Livestock are protected from short-term deprivation of vitamin A by their ability to accumulate the vitamin in the liver; however, it is estimated that the intake required to initiate storage is at least three times the minimum daily intake.[1189] Vitamin A—replete cattle fed a diet devoid of vitamin A require approximately 180 days before they begin to show clinical signs. During that time the cattle grow and fatten normally and show no adverse effects. Offspring born to these animals may show severe deficiencies. Papilledema and blindness develop rapidly after the hepatic stores are depleted.[1189] An interesting sexual dimorphism in susceptibility to dietary deficiency of vitamin A was found in one study of feedlot cattle; although all cattle were fed the same deficient diet, only steers had clinical signs.[1190]

Vitamin A deficiency may be categorized as a primary or a secondary condition. Primary deficiencies of vitamin A develop in cattle confined in drylot corrals or pasture on dry grass forage for prolonged periods or when cattle are kept indoors and fed unsupplemented, vitamin-depleted cereals and dry forage in which the activity of carotene has been destroyed. Also, there is a seasonal difference in the concentration of vitamin A in feedstuffs. For example, cattle grazed on green pastures are consistently replete with the vitamin, whereas those grazed on dry pastures at the end of summer may become marginally deficient. Approximately 80% of the vitamin A concentration of hay is lost during field curing.[1192]

Destruction of carotene is hastened by many environmental and physical factors, including heat, sunlight, trace mineral supplements, and humidity. In one study, exposure of nine different supplements to trace minerals in a humidified atmosphere (60% relative humidity) at 28°C (82.2°F) resulted in depletion of 47% to 92% of the total vitamin A after 1 week of incubation.[1193] Improper storage has been implicated as the cause of the depletion of vitamin A in one field case.[1189] Other factors that affect the stability of vitamin A in feedstuff include pelleting and exposure to rancid fat in the feed. The addition of gelatin to vitamin premixes has been recommended to stabilize the vitamin A activity in feed.[1184,1194]

Secondary deficiencies of vitamin A result from interference with vitamin absorption, inhibition of the conversion of β-carotene to retinol (vitamin A) in the small intestine, or an increased requirement in the face of limited vitamin intake. The conversion of carotene to retinol is impaired in vitamin A—deficient patients.[1179] Sheep may be more resistant to vitamin A deficiency because they convert β-carotene more efficiently than cattle.[1179] Extensive destruction of preformed vitamin A by microflora appears to occur in the rumen and the abomasum.[1194–1197] Microbial destruction, fever, lactation, high ambient temperatures, and inadequate dietary energy may increase the daily requirement for vitamin A.[1198] Females are slightly more resistant to the vitamin deficiency than males, presumably because of the interconversions of estrogenic hormones into vitamin A.

Secondary deficiencies of vitamin A may be caused by impaired vitamin absorption, which may occur from long-term feeding of mineral oil. Ingestion of highly chlorinated naphthalenes (X disease) causes severe vitamin A deficiency as a result of interference with the conversion of carotene to vitamin A. Some in vitro evidence indicates that a high level of dietary nitrates inactivates intraruminal vitamin A by oxidation. This may not be clinically important, however, because studies performed in vivo failed to show a greater requirement for the vitamin when animals were fed subtoxic doses of nitrates.[1197–1202] Other factors that can affect availability of vitamin A or the requirement for the vitamin include diets with low forage content, high proportion of corn silage to hay in the diet, increased exposure of animals to pathogens, and periods where immunocompetence is reduced (e.g., peripartum period).[1191] Challenges to the immune system increase the requirement for vitamin A.

35.2.36.6 Necropsy Findings

The major pathologic changes in the fundus of vitamin A—deficient calves include papilledema, small flame-shaped hemorrhages around the optic disc, venous congestion in the area of the swollen optic disc, degeneration of the retinal ganglion cells, focal retinal thinning, and fusion of parts of the retina to the choroid plexus.[1182] Other changes associated with vitamin A deficiency include doming of the frontal bones, enlargement of the carpi, cerebellar and cerebral compression, partial transtentorial herniation of the cerebellum, cystic dilation of the hypophyseal cleft, focal ruminal hyperkeratosis, and increased keratinization of the squamous epithelium of the penile and the preputial mucous membrane.[1203,1204] Corneal ulceration and clouding have been observed in the eyes of calves with naturally occurring deficiencies.[1175,1185] Vitamin A deficiency also can cause anasarca, squamous metaplasia of the salivary ducts, degeneration of the germinal testicular epithelium, degenerative changes in the intestinal epithelium in lambs, and reduction in intramuscular fat in cattle.[1204–1206]

Microscopic changes in the CNS include attenuation of the optic nerve with necrosis and demyelination. Focal accumulations of phagocytic cells containing lipofuscin and hemosiderin are present in the necrotic

area. The optic nerve is attenuated along its entire length. Gliosis and focal vacuolization of the nerve also are seen, as is a focal loss of granular and molecular layers and Purkinje's cells in the cerebellum. The meninges are thickened by fibrosis and mononuclear cell inflammation. The microscopic changes in the bones include wider than normal spacing of the central canals and reduction of osteoclastic lacunae.

35.2.36.7 Treatment and Control

Cattle with severe blindness caused by damage to the retina or optic nerves do not regain their vision when treated with vitamin A; however, cattle with acute encephalopathy and simple papilledema may respond favorably after a short period of vitamin supplementation.[1189] Affected cattle should receive 440 IU/kg (1 IU = 0.4 µg) of vitamin A parenterally and then 6000 IU/kg parenterally every 50 to 60 days until the diet has been enriched. High-dose oral therapy is important because carotene and oil suspensions of vitamin A are not efficiently used when administered by parenteral injection.[1207] Administration of large doses orally is important because conversion of β-carotene to vitamin A is inhibited in deficient calves. The recommended concentration of vitamin A in milk replacers for preruminant calves is 11,000 IU/kg dry matter.[1180]

Prophylactic dietary supplementation of vitamin A should be considered in all cattle that lack access to green feed. Dietary supplements could include leafy, freshly cured hay, green pasture, or 0.5 to 2 kg of alfalfa meal daily. Concentrate feeds formulated with exogenous, stabilized vitamin A are commercially available. 1029
Vitamin A powder* may be added to the drinking water at a rate of 425,000 U/50 gallons. This treatment 1030
should be continued for as long as the dietary deficiency exists. The recommended vitamin A requirements in cattle are 80 IU/kg for growing animals and 110 IU/kg for adult animals (including pregnant and lactating cows). Recommended concentrations (IU/kg dry matter) of vitamin A in feed are 2200 IU for feedlot cattle, 2800 IU for pregnant cows, and 3900 IU for lactating cows.[1191]

Subclinical deficiencies in ewes have been treated with a vitamin-mineral premix containing 0.3 to 0.27 kg iodine, 20.6 kg zinc, 7.9 kg copper, and 1644.5 million IU vitamin A per ton of feed. Addition of this premix to the diet of a group of sheep increased their productivity, as measured by viability, birthweight and rate of gain of lambs, and amount and quality of wool.[1208]

35.2.37 HYDROCEPHALUS AND HYDRANENCEPHALY OF RUMINANTS

35.2.37.1 Definition and Etiology

Hydrocephalus/hydranencephaly is a common occurrence in large ruminants. It is underdiagnosed because many of the affected animals die of complications, and the primary condition is overlooked during clinical and pathologic examinations. One study reported that 97 of 155 calves with CNS lesions had hydrocephalus.[1209] Hydrocephalus may be classified as hypertensive or normotensive.[1210]

35.2.37.1.1 NORMOTENSIVE HYDROCEPHALUS (HYDRANENCEPHALY)

Normotensive hydrocephalus that develops as a result of a failure of cell growth or cellular necrosis is called *hydranencephaly*.[1210] Most cases of hydranencephaly in domestic livestock are caused by in utero infection of the fetus by the bluetongue, bovine viral diarrhea (BVD), akabane, Cache Valley, aino, or

border disease virus.[1209,1211–1217] The pathogenesis and epizootiology of the multisystemic virus infections bluetongue and BVD are discussed in detail in Chapter 32. The neurologic effects of border disease virus infection are discussed earlier in this chapter.

The loss of neurons results in flexural contractions of the limbs (arthrogryposis) and inability to nurse. The calves appear blind and are unaware of their surroundings. They usually are unwilling to stand and display a weak suckle. They may exhibit a dysphonia, which resembles a bark. Neonates that are unable to nurse are deprived of colostrum and die of septicemia by 4 days after birth.

35.2.37.2 Akabane Virus Infection

The akabane virus is a member of the Sindbis serologic subgroup of the Bunyaviridae family of the Arboviridae.[1211] It has been isolated from cattle in Africa, Japan, Israel, Korea, and Australia.[1212–1217] The host range of akabane virus includes sheep, cattle, and goats. Infection of pregnant, nonimmune dams results in hydranencephaly or arthrogryposis of the fetus.[1218] The disease is thought to be transmitted to the cow by various *Culicoides* species. Experimentally infected calves develop porencephaly and encephalitis when exposed to the akabane virus between gestational days 62 and 96.[1219] Studies in naturally infected cattle showed that infection of calves between days 76 and 104 of gestation resulted in hydranencephaly or porencephaly, whereas infection between days 103 and 174 of gestation resulted in arthrogryposis.[1220] Lambs are susceptible when exposed to the virus on gestational days 30 to 36.[1217] Fetuses that survive the in utero infection are born with arthrogryposis. The CNS lesions apparently are the result of a direct necrotizing effect of the virus on the developing neurons. The pathologic changes of the CNS in experimentally infected calves and lambs are similar to those of naturally acquired infections.[1214,1217] Adults occasionally abort when infected by the virus but do not develop clinical disease.

A syndrome of arthrogryposis, facial deformities, kyphoscoliosis, hydranencephaly, and hypoplasia of multiple regions of the brain and spinal cord has been described in Corriedale sheep in Australia. Although resembling the disorder caused by congenital akabane virus infection, breeding trials supported an autosomal recessive inheritance for the disease.[1221]

35.2.37.3 Aino Virus Infection

The aino virus causes stillbirths, premature calving, and congenital malformations, including arthrogryposis, cerebellar hypoplasia, and hydranencephaly, in calves of Japan and Australia.[1222–1224] Aino virus is antigenically and biologically distinct from akabane virus, but the clinical syndromes of fetal infection by the two viruses are indistinguishable.

35.2.37.4 Chuzan Virus Infection

Hydrocephalus, hydranencephaly, and cerebellar hypoplasia have been attributed to infection of pregnant cattle with the Chuzan virus.[1225–1227] This virus is a relative of the akabane and aino viruses and is classified as a new member of the Palyam subgroup of the genus *Orbivirus*. The virus has been isolated from *Culicoides oxystoma,* which may serve as the major vector. The clinical signs are characteristic of hydrocephalus.

35.2.37.5

Cache Valley Virus Infection

A flock outbreak of arthrogryposis, myositis, hydranencephaly, and a variety of other brain malformations (micrencephaly, cerebellar hypoplasia, porencephaly) in newborn lambs in the southwestern United States was attributed to in utero infection with the Cache Valley virus (family Arboviridae).[1228,1229] Cache Valley virus was first isolated from mosquitoes from Utah and has since been isolated from caribou, horses, sheep, and cattle elsewhere. Antibodies have been found in white-tailed deer in the southwestern United States, but the role of this mammal in the survival of the virus and the transmission of the disease to livestock is unknown.[1230] In one survey of sheep in the western United States, the seroprevalence for the Cache Valley virus was 19.1%.[1228] Vectors for the virus include *Anopheles, Aedes, Culex,* and *Coquellettidia* mosquitoes.[1231] Infection before 30 days of gestation may cause embryonic death, whereas infection between days 30 and 52 causes fetal malformations.[1231]

35.2.37.6

Bluetongue Virus Infection

The bovine fetus is most susceptible to the development of hydranencephaly from bluetongue virus when the dam is infected at approximately 125 days of gestation.[1232,1233] Abortions occur when nonimmune dams are infected at other times of gestation. Serotype 11 or serotype 17 of the virus is most frequently isolated from calf and lamb neonates in field epizootics.[1233] Calves infected in utero may develop one or more associated birth defects, including hydranencephaly, arthrogryposis, brachygnathia, prognathia, and excessive gingival tissue. In vitro studies have not supported the role of infected calves as reservoirs for the virus.[1234] Similar abnormalities and fetal deaths have been reported following vaccination of pregnant ewes with live attenuated virus.[1235] (See Chapter 32 for additional information.)

35.2.37.7

Bovine Viral Diarrhea Virus Infection

Hydranencephaly, hydrocephalus, and cerebellar hypoplasia have been associated with fetal infection of cattle with the BVD virus.[1236–1239] Precolostral serum antibody titers for the virus in affected calves vary; some titers range from 1:32 to 1:256, but other calves may have persistent viremias yet no demonstrable antibody. The BVD antibody titer in CSF may range from 1:4 to 1:32. The virus can be isolated from approximately 12% of affected calves.

35.2.37.8

Other Infectious Agents

A single case of hydrocephalus in a calf aborted at 7 months of gestation was associated with necrotizing encephalitis caused by *Neospora caninum*.[1240]

35.2.37.8.1

HYPERTENSIVE HYDROCEPHALUS

An increase in CSF volume that results from compressive or obstructive lesions in the ventricular system or from decreased CSF absorption is called hypertensive hydrocephalus.[1210] Obstructive lesions of the ventricular system trap the CSF in the ventricles, causing an increase in CSF volume and pressure. Ischemia and CNS degeneration result from the high CSF pressure. The sites of obstruction most often

include the lateral apertures, mesencephalic aqueduct, lateral ventricles, interventricular foramina, and fourth ventricle. The obstructions may be either congenital or acquired. Causes of acquired obstructive hydrocephalus include cerebral abscess, cholesteatoma (equines), equine infectious anemia, *Coenurus cerebralis* infestation, pachymeningitis, and lymphosarcoma. Hypertensive hydrocephalus also may be caused by acute inflammatory disease such as meningitis and vitamin A deficiency. In these diseases the increased pressure is the result of impaired CSF resorption.

35.2.37.8.2

CONGENITAL HYPERTENSIVE HYDROCEPHALUS

Congenital hypertensive hydrocephalus is a hereditary condition seen in Hereford, Charolais, Ayrshire, Dexter, Holstein, and Jersey calves.[1241–1243] The condition also has been recognized in Arabian foals.[1244]

At least six forms of congenital hypertensive hydrocephalus (types I through VI) have been identified in cattle.[1245] Type I is a communicating hydrocephalus that is unrelated to dwarfism and apparently has a hereditary basis.[1241] The mode of inheritance is thought to be a single autosomal recessive character. In highly inbred herds the prevalence of heterozygotes may exceed 20%. Pathologic lesions of this form of hydrocephalus included cranial doming and enlargement of the cerebral cortex and the choroid plexus. All affected calves die by 5 weeks of age.

Type II occurs in Herefords and is characterized by dorsal kinking of the mesencephalon and stenosis of the sylvian aqueduct, without cranial doming. Ventricular dilation is less than that described for type I hydrocephalus.

Type III also occurs in horned Hereford cattle. This type is similar to type II, except that cerebellar hypoplasia, microphthalmia, and muscular degeneration are observed. These are not characteristics of the type II hydrocephalus.

Type IV occurs in white shorthorn calves. The disease is considered to be heritable through either an autosomal recessive gene or a dominant gene with incomplete penetrance. Affected animals develop an obstructive hydrocephalus, microphthalmia, and scoliosis of the thoracolumbar spinal column. Ocular lesions associated with the disease include persistent pupillary membranes, retinal detachment, retinal dysplasia, vitreous hemorrhage, and hypoplasia of the optic tracts. A misshapen sylvian aqueduct apparently causes the fluid accumulation.

Type V is a form of hydrocephalus with congenital achondroplasia that has been reported in Dexter and Jersey calves. The disease is considered to result from a recessive genetic trait. The calves are either aborted or stillborn. Animals that survive to term have arrested development of the nasal bones and maxillae. Anasarca, achondroplasia, kyphosis, and cleft palate also are seen.

Type VI is a form of internal hydrocephalus of Holstein-Friesian calves. The animals are born dead or die shortly after birth. The pathologic abnormalities include fluid enlargement of the lateral ventricles with normal cranial development.[1244] The condition is thought to be hereditary.

35.2.37.9

Clinical Signs

Hydrocephalic animals often are born dead or are weak and die shortly after birth. The most obvious signs in animals that survive include failure to bond to the dam, depression, diminished learning ability, partial failure of suckling, droopy head and ears, muscular fasciculations, head tremor, conscious proprioceptive deficits,

blindness, ventrolateral strabismus, nystagmus, dysphonia, tongue flaccidity or paralysis, retention of food material in the cheeks and lips, limb spasticity, hyperreflexia, psychomotor seizures, recumbency, and coma. Occasionally, doming of the calvarium or protrusion of fluid-filled cystic structures through an open fontanelle is seen.[1246] Affected neonates often do not ingest sufficient amounts of colostrum and frequently die of septicemia.

In virally induced cases of hydranencephaly, associated skeletal deformities may be observed, including abnormally curved ribs, kyphoscoliosis, flexural deformities of the limbs, domed skulls, and brachygnathia. Patients with hydrocephalus caused by compressive lesions around the ventricular system may show unilateral or bilateral signs of increased intracranial pressure. The clinical signs of unilateral lesions include head tilt (toward the lesion side), ipsilateral mydriasis, and contralateral menace deficit. Signs of hydrocephalus in foals are similar to those in calves. The cause of the condition in horses is unknown.

Antemortem diagnosis of brain malformations has been facilitated by CT and MRI. However, these techniques are rarely warranted or available for use in large animal species. A more practical technique for using ultrasonographic imaging, transorbital echoencephalography, has recently been described and has proved effective for the diagnosis of hydranencephaly.[1247]

35.2.37.10 Clinical Pathology

The diagnosis of hydrocephalus in calves and lambs is typically based on the presence of characteristic clinical signs and a domed skull. Whenever hydranencephaly is suspected, blood should be collected for virus isolation, serologic testing, and quantitative immunoglobulin determination. Presuckle serum samples from bovine fetuses that have been infected by the akabane or bluetongue virus in the latter part of gestation may be seropositive. Immunologically competent calves that are infected with the bluetongue virus have serum neutralization indices ranging from 2.5 to 4.[1230]

35.2.37.11 Necropsy Findings

The pathologic lesions of hydranencephaly are similar regardless of the etiologic agent. They include microcephaly, cerebellar hypoplasia, hydrocephalus, hydranencephaly, and porencephaly of the cerebral and the cerebellar cortex. Microscopic lesions of hydranencephaly include segmental loss of dorsolateral ventricular ependyma, thinning of the periventricular white matter, porencephalic cysts, and nonsuppurative meningoencephalitis. Lesions in other parts of the CNS may include loss of ventral horn cells in the spinal cord and demyelination in the spinal cord. Nonsuppurative inflammatory changes may be seen in cases caused by viral infections. Polymyositis has been described in affected calves; however, it is unclear if these lesions are caused by viral infection or occur secondary to the denervation. The skeletal deformities associated with virally induced hydranencephalies include rigid extension or contraction of one or more limbs (arthrogryposis), abnormally curved ribs, domed skull, thickening of the calvarium, kyphoscoliosis, and brachygnathia.

35.2.37.12 Treatment

1031
1032

Except for one report of successful surgical intervention in a calf with a meningocele, no satisfactory therapy is available for the treatment of hydrocephalus or hydranencephaly in large animals.

35.2.38 AMMONIATED FORAGE TOXICOSIS (COW BONKERS)

Exposure of poor-quality forage to anhydrous ammonia improves the nutritional density of the material and reduces certain toxic fungal metabolites, specifically the prolactin-like toxins of the endophytic fungus *Acremonium coenophialum*.[1248] Ammoniation increases dry matter intake, enhances digestibility, and increases the relative value of the protein content of the feed. However, overammoniation of the forage, at a rate exceeding 3% of the forage on a dry matter basis, may result in toxicosis. Studies now suggest that several dialkylimidazoles may be responsible for the neurotoxic effects of ammoniated feedstuffs, superseding previous theories that 4-methylimidazole is the primary neurotoxin.[1249,1250] Ammoniated foodstuffs containing high levels of molasses are more toxic than similarly treated grass hay. The toxin may be concentrated in milk; consequently, calves suckling from normal-appearing dams may show clinical signs of intoxication.

Affected animals are hyperesthetic and ataxic. At rest the animals assume a sawhorse stance, but when excited, they become hyperactive, appear to be blind, and circle propulsively. Other clinical signs include vocalization, dysphonia, and walking or running into objects. The periods of frenzy may result in recumbency and convulsions. The spasmodic episodes last for 15 to 20 minutes. Afterward the animals rest quietly, with occasional muscle tremors. Repeated occurrences of the mania may be precipitated by loud noises or other frightening experiences. The concentrations of ammonia in the cerebrospinal fluid (CSF) and blood may be increased. In one report, blood and CSF concentrations of ammonia were 8.16 and 1.05 μg/mL, respectively. Levels of interleukin-6 (IL-6) are elevated in the CSF of affected calves, but not in the systemic circulation.[1251] IL-6 is hypothesized to play a key role in ammoniated forage toxicosis. Although specific treatments have not been identified, one report indicated that affected calves benefited from acepromazine (0.045 mg/kg IV) and thiamine (1.14 mg/kg IM).[1252]

35.2.39 LEAD POISONING

35.2.39.1 Definition and Etiology

Lead poisoning in ruminants is characterized by an acute encephalopathy. In contrast, lead poisoning in horses is characterized by chronic polyneuritis. Blindness, ataxia, and depressed sensorium are significant clinical signs in cattle, sheep, and goats, whereas in horses the poisoning is associated with weight loss, dysphagia, and secondary aspiration pneumonia. Cattle most often are poisoned because of their tendency to lick or chew on foreign objects, their access to lead-containing materials, and their propensity to drink contaminated petroleum distillates.[1253]

35.2.39.2 Clinical Signs

The signs of lead poisoning in ruminants are characteristic of central nervous system (CNS) derangement. During the first stages of lead poisoning, affected cattle stand alone and are depressed.[1254] They may show hyperesthesia, muscular fasciculations, and rapid, spastic twitching of the eyelids or other facial muscles. Progression of the disease is associated with ataxia, conscious proprioceptive deficits, blindness, head pressing, odontoprisis, coma, and convulsions.[1255,1256] Despite the blindness, the pupillary reflexes usually are normal. Some animals may display episodic running, hyperesthesia, and bellowing. Others may die suddenly without premonitory signs. The more acute and severe the toxicity, the more acute, severe, and

excitatory are the clinical signs.[1257] Animals with subacute or chronic lead poisoning have signs that are less excitatory and more indicative of CNS depression and have a longer clinical course. Affected cattle may accumulate frothy saliva at the commissures of the lips. Gastrointestinal (GI) signs of bloat, diarrhea, rumen atony, and colic occur in about 60% of lead-poisoned cattle, and the presence of such signs increases the index of suspicion for lead toxicity versus other causes of cerebral dysfunction.[1258] Other substances ingested with the lead may contribute to GI disturbances. The clinical signs of lead poisoning in horses include weight loss, lack of coordination, laryngeal or pharyngeal paralysis, dysphonia, roaring, conscious proprioceptive deficits, loss of anal tone, facial paralysis, and difficulty with mastication.[1259] Aspiration of pharyngeal debris caused by dysphagia may result in pneumonia. Fine muscular tremors occur intermittently. The poisoned animals die in psychomotor seizures. Horses with lead poisoning are emaciated at death.[1260]

In cattle, lead produces microscopic changes of the myocardium that result in arterial hypertension (120 to 150 mm Hg) and electrocardiographic abnormalities. These electrical changes, which occur by 30 days after exposure, include increased duration and amplitude of the P wave (0.16 second and 0.06 mV, respectively), prolongation of the PR interval (0.14 to 0.16 second), decreased QT interval (0.32 second), and inverted T wave in lead II.[1261]

35.2.39.3

Clinical Pathology

Diagnosis of lead poisoning is based on measurement of increased blood and tissue concentrations of lead. Tissue levels of lead in naturally poisoned cattle can reach 20 to 100 ppm in the liver, 30 ppm in the kidneys, and 5000 ppm in bone. Reported reference blood lead concentrations vary considerably, ranging from 0.05 to 2.5 ppm.[1255,1256,1262] Suggested toxic ranges also vary considerably among laboratories. Reference values from earlier colorimetric studies are consistently higher than those from later tests using spectrophotometry.[1263] Modern techniques usually report 0.3 ppm as the maximum normal blood lead concentration. When interpreting the results of a lead measurement, consideration of the reference ranges obtained with similar methodology is essential. Table 35-12 compares the lead concentrations of various tissues of experimentally poisoned and control calves. Heparin is the anticoagulant of choice when collecting blood for lead measurement because it does not chelate the lead. The lead concentration of ruminal fluid from acutely poisoned cattle ranges from 0 to 11,875 ppm.[1255]

Livestock that are chronically poisoned with low concentrations of lead may have a normal blood lead concentration but a high concentration in the bone. In these cases the poisoning can be diagnosed by administration of calcium disodium ethylenediamine tetraacetic acid (EDTA), which solubilizes the bone lead stores and increases the concentration of lead in the plasma. The soluble lead-EDTA complexes are excreted in the urine. The urinary lead concentration may rise by 40-fold over pretreatment levels within a few hours. Table 35-13 shows the lead concentrations in the urine and blood of naturally exposed horses and the temporal changes that occur after treatment with calcium disodium EDTA (75 mg/kg). In cases of chronic lead poisoning, radiographs of the abdomens of smaller patients may reveal lead-containing radiodense foreign material in the GI tract.[1264] “Lead lines” also may be present in the long bones of young animals chronically exposed to lead.

Table 35-12 Mean Lead Concentration (and Range) in Calf Tissues after Exposure to Different Dosages of Lead Acetate for 7 to 20 Days

	Dosage of Lead Administered		
Tissue	**Control ± SD**	**2.7 mg/kg (ppm) ± SD**	**5 mg/kg (ppm) ± SD**
Bone	0.22 ± 0.07	49.2 ± 14.15	54.92 ± 20.15
	(0.18–0.32)	(30–75.34)	(32.63–105.81)
Kidney	0.11 ± 0.02	49.49 ± 32.54	88 ± 19.5
	(0.09–0.13)	(20.72–90.36)	(51.55–114.24)
Liver	0.13 ± 0.04	19 ± 11.76	30.51 ± 11.67
	(0.09–0.18)	(5.42–29.96)	(15.13–54.98)
Cerebrum	0.07 ± 0.02	0.66 ± 0.16	0.81 ± 0.27
	(0.06–0.1)	(0.54–0.89)	(0.5–1.18)
Blood	0.03 ± 0.01	0.47 ± 0.29	1.57 ± 0.62
	(0.03–0.04)	(0.3–0.9)	(1.08–3.21)

* Values given in ppm; numbers reflect the range of observations.

† Dosage of 75 mg/kg body weight.

When blood lead concentrations are normal in chronically poisoned animals, measurement of free erythrocyte porphyrins and erythrocyte concentrations of α-aminolevulinic acid (ALA) are the preferred

methods of diagnoses. The concentration of porphyrins is increased in the blood, urine, and feces of animals with lead poisoning. The reference range of blood porphyrin concentrations in normal calves is 21.6 ± 11.6 to 45.6 ± 10.3 μg/dL for whole blood and 113 and 142.8 ± 32.4 μg/dL for erythrocytes.[1256,1265,1266] In chronically exposed, asymptomatic cattle, the free erythrocyte porphyrin concentrations are frequently greater than 2000 μg/dL. A field test has been developed for determining blood porphyrins.[1266]

Reference ranges for ALA dehydrase are 45.8 ± 20.6 U, whereas activities ranging from 28 to 33 U have been reported in naturally exposed calves.[1260] The urinary concentration of δ-ALA is increased and range above 500 μg/mL.[1261,1267,1268] Measurement of ALA in the erythrocytes is more reliable than measurement in urine.[1269]

Environmental sources of lead can be detected by direct measurement of the lead concentration of the soil or pasture forage. Forage from toxic pastures contains more than 30 ppm of lead, and in some cases the level may exceed 300 ppm.[1268,1270]

The hematologic abnormalities of lead poisoning are subtle. Most poisoned livestock have a normal hemogram. If present, lead-related changes are characteristic of a hemolytic anemia with an inappropriately large-bone marrow response. The morphologic abnormalities of erythrocytes include anisocytosis, poikilocytosis, polychromasia, hypochromia, Howell-Jolly bodies, metarubricytes, and basophilic stippling.[1255,1271] The shape changes begin within hours after ingestion of the lead and peak by 100 days.[1255,1271] Blood changes do not occur in all cases of the disease and are not necessarily specific indicators of lead poisoning in cattle, in which elevated blood lead may be present without hematological abnormalities.[1272] However, hematologic abnormalities tend to be more consistent in chronic lead toxicity and in lead-poisoned horses.

Lead toxicity has a variety of effects on endocrine function in cattle. Elevated levels of serum T_3, T_4, estradiol, and cortisol have been demonstrated in cattle with elevated blood lead levels.[1273] Parameters of liver function also are affected; serum alanine and aspartate transaminase (ALT and AST) levels are increased, whereas serum lipids, total protein, and albumin are decreased.

In poisoned animals the concentrations of protein and WBCs in CSF are increased, ranging from 50 to 100 mg/μL of protein and 5 to 50 mononuclear cells/mL, respectively. Such changes are relatively nonspecific and found with other causes of polioencephalomalacia.

35.2.39.4

Pathophysiology

Lead enters the body through the GI tract or less often through the respiratory tract. Metallic lead and the sulfide form are less well absorbed than the acetate, phosphate, carbonate oxide, and hydroxide salts. Metallic lead is poorly absorbed and causes toxicity only when a lead foreign body becomes entrapped in the stomach for prolonged periods. Interaction between lead and other minerals may occur. For example, high levels of dietary calcium reduce the GI absorption of lead. Concomitant exposure to lead and cadmium results in a worsening of the clinical signs of lead poisoning.[1274]

Acute toxic single doses of lead range from 200 to 600 mg/kg for calves and 600 to 800 mg/kg for adults.[1275,1276] Although intestinal absorption of lead is relatively inefficient, significant amounts can cross into the blood if sufficient quantities are ingested. Approximately 1% to 2% of the total oral dose of lead is absorbed

by 24 hours.[1255] Increases in the blood lead concentration are observed as early as 3 hours after dosing. Most of the lead absorbed from the digestive tract (90%) is bound irreversibly to erythrocyte proteins, resulting in a low lead concentration in the plasma but higher concentrations in whole-blood specimens.[1277] At the end of the erythrocytes' lifespan, the cell-bound lead is metabolized from the erythrocyte proteins and deposited in the bone as the triphosphate salt. A smaller amount of dissolved lead is deposited into the soft tissues as the diphosphate. A portion of the soft tissue lead is excreted through the GI tract via the secretions (pancreatic juices, bile) and direct diffusion. The half-life of blood lead in adult cattle is extremely variable and unpredictable, ranging from 48 to 2507 days in one study.[1278] Phenotypic or genotypic factors may affect metabolism and storage of lead; for example, beef cattle store more lead in the liver than the kidneys compared to dairy cattle.[1279] The variable time for clearance of lead has an obvious implication for public health, because all carcasses of animals suspected or known to be exposed to lead must be tested before being cleared for human consumption.[1280]

1033 1034

Lead also crosses the placental barrier and accumulates in fetal bone, liver, and kidneys, but does not substantially accumulate in milk. Infertility, abortions, and fetal malformations may result from exposure to lead.[1257] The concentration of lead in milk from lactating cattle fed a daily dose of 13 mg of lead acetate remains less than 5.9 parts per billion (ppb).[1281] In one study a logarithmic relationship between blood and milk lead concentrations was found. At blood concentrations below 3.6 µg/dL, milk lead concentrations were 0.8 µg/mL. However, cattle with higher blood lead levels (4.8 µg/dL) had exponentially greater concentrations in milk (2.2 µg/kg).[1282] Lead cannot be detected in milk by 7 months after exposure.[1283]

The toxic effects of lead include inhibition of free sulfhydryl groups found in many enzymes, interference with zinc-containing metalloproteins, and steric inhibition of enzyme activity.[1271] Enzymes of heme synthesis are particularly susceptible to injury. These include δ-ALA dehydratase and ferrochelatase. Interference with ferrochelatase inhibits the formation of heme from protoporphyrin, resulting in a buildup of unmetabolized porphyrins, including protoporphyrin I, uroporphyrins, and coproporphyrins. The last two molecules are excreted in the urine and feces, respectively.[1254] Protoporphyrin I is retained in the erythrocyte.

Interference with the activity of ALA dehydrase may be partly responsible for the brain damage associated with lead poisoning. The enzyme δ-ALA dehydrase combines two molecules of δ-ALA into a single porphobilinogen molecule. This enzyme is exquisitely sensitive to lead. Inhibition of the enzyme leads to accumulation of ALA, which is excreted into the urine. Concentrations of the synthetic product porphobilinogen in the erythrocytes are reduced.[1266,1267,1269,1284]

Because of the interference with heme metabolism and the altered function of other erythrocyte proteins, the erythrocyte half-life is shortened, which may result in a normochromic, normocytic anemia in a small proportion of chronically poisoned animals.[1284] Iron is not adequately used and is stored in sideroblasts in the bone marrow.[1266] Lead also interferes with the activity of pyrimidine-specific 5′-nucleotidase.[1285] Loss of activity of this enzyme results in basophilic stippling.

After absorption, lead rapidly enters the brain at a dose-dependent rate. The lead deposition in the CNS results in acute cerebellar hemorrhage and edema from capillary dysfunction.[1277] Abnormalities of brain cerebroside content and catecholamine metabolism have also been described in animals with lead poisoning; however, the role of these changes in the pathogenesis of the clinical signs is unknown. The pathogenesis of lead encephalopathy is multifactorial. Encephalitic signs probably originate from a combination of decreased

microvasculature, cellular necrosis, brain swelling, neurotransmitter dysfunction, and decreased glucose uptake by the brain.[1286]

The molecular effects of lead on the myocardium are unknown. Hypertension caused by chronic poisoning is thought to result from an inhibition of sodium-potassium adenosine triphosphatase or an alteration of the juxtaglomerular apparatus.[1261]

Ingestion of lead also results in aberrations of other minerals. For example, long-term exposure to lead results in competitive inhibition of selenium uptake, thereby diminishing the absorption of selenium by as much as 26%.[1276] If selenium intake is marginal, lead toxicosis could manifest as an outbreak of white muscle disease. Lead-induced selenium deficiency may contribute to the pathogenesis of myocardial disease and immune system dysfunction.

35.2.39.5

Epidemiology

Sources of lead are legion, including lead arsenate defoliants, batteries, used motor oil, linoleum, roofing felt, paint, machinery grease, caulking compounds, improperly compounded mineral supplements, and foliage near lead smelters and battery-recycling plants.[1254,1260,1268,1287–1293] Blood lead levels of animals residing in highly contaminated urban environments may be significantly greater than those of their rural-dwelling counterparts, and high lead levels have been reported in grasses growing near busy roadways, but the clinical significance of these findings is unclear.[1290,1294,1295] Contamination of preserved feeds, such as silage, can occur before or during processing or during storage. Factors that can increase the likelihood of ingestion of lead-contaminated foodstuffs include lack of alternative feed, hunger, and phosphorus deficiency.[1257] The single lethal dose of lead for cattle is estimated to range from 220 to 600 mg/kg for calves, 600 to 800 mg/kg for adult cattle, and 400 mg/kg for goats.[1257,1275] Poisonings from cumulative intake are associated with substantially lower daily doses. Although cattle can detect fairly low levels of lead on pasture and have an aversion toward contaminated herbage, continued exposure may lessen this aversion, making animals more prone to ingest contaminated material.[1296] Lead poisoning has been induced in cattle by feeding 5 to 6 mg lead/kg body weight/day for 3 years or 6 mg/kg of lead (lead acetate) for 7 days.[1268,1297] Lead poisoning has been reported in cattle exposed naturally to 6 to 7 mg/kg/day of lead on foliage and in calves given oral lead acetate at 2.7 to 20 mg/kg/day.[1297] The interval for development of clinical signs ranges from 5 to 20 days and is related to the dose and the ionic form of lead administered.[1297] Ensiling of contaminated forage results in percolation and concentration of lead at the bottom of the silo.[1298]

The toxicity of lead is apparently influenced by dietary factors. Calves on a milk diet are more susceptible to lead poisoning than calves fed hay and grain.[1262] There appears to be a direct correlation between high levels of vitamin D and enhanced lead absorption, which may explain the greater occurrence of the poisoning during the summer. Elevated copper concentrations in forage, such as may be found in pastures fertilized using pig slurry, may potentiate accumulation of lead in animals consuming it.[1299]

The estimated cumulative toxic dose of lead for horses is 2.9 mg/kg/day.[1300] Poisonings have been reported in horses grazing pastures contaminated with 320 to 440 ppm of lead from a metal smelter; this amounted to a daily intake of 2 g (~6.4 mg/kg). Metallic lead and the “galena” (insoluble sulfide salt) are less toxic than the acetate and carbonate lead salts.[1301]

1034 1035

35.2.39.6

Necropsy Findings

The macroscopic brain lesions of lead poisoning are mild and include brain edema, congestion of vessels of the cerebral cortex, and yellowish discoloration and flattening of the cortical gyri. Lesions tend to be most severe in the occipital lobes. Microscopic changes in the brain include capillary prominence, endothelial cell swelling, edema of the Purkinje cell layer of the cerebral cortex, laminar cortical neuronal necrosis, and edema of the white matter.[1302] The lesions are predominantly located on the tips of the gyri. Whether these lesions are caused by a direct effect of lead on the neurons or from vascular damage is unclear.[1277] Intranuclear acid-fast inclusion bodies in the renal tubular epithelial cells have been described in experimentally poisoned cattle. Chronic lead exposure also may interfere with normal functioning of the immune system, resulting in an increased susceptibility to infections.[1303]

35.2.39.7

Treatment

Therapy for lead poisoning should include removal of the lead from the digestive tract, chelation therapy with calcium disodium EDTA, and fluid and nutritional support of the patient. Treatment with calcium disodium EDTA (calcium versenate) has been shown to be superior to treatment with penicillamine or dimercaprol (BAL). The EDTA chelates osseous but not soft tissue—bound lead.[1274] After chelation the unsaturated bone stores reequilibrate with the lead remaining in the soft tissues. In cases of acute lead poisoning, several days are required before reequilibration results in a decreased blood lead concentration. The dose of calcium disodium EDTA is 66 mg/kg/day, divided into several doses daily for 3 to 5 days.[1304] After five daily treatments, a 2-day nontreatment period is recommended to reequilibrate the soft tissue and bone lead. After the 2 days' rest, daily treatments are given for another 5 days. The decision to continue therapy with EDTA should be based on the results of posttreatment blood lead analyses and renal function tests. Another recommendation is for administration of two IV injections of calcium disodium EDTA (110 mg/kg per dose) given 12 hours apart for 2 days.[1305] Therapy then is withheld for 2 days, after which the EDTA treatments are reinstituted for 2 more days. The comparative efficacy of this regimen is unknown.

The EDTA also chelates other divalent cations. Consequently, prolonged administration of the drug results in trace-mineral deficiencies, especially of zinc. For this reason, after prolonged EDTA therapy, oral supplementation with zinc should be considered to prevent the development of parakeratosis.

Meso-2,3,-dimercaptosuccinic acid may be a more effective agent for lead chelation, particularly when it comes to removing lead from soft tissue.[1306] However, experience with this drug is still limited. There appears to be no advantage to using this drug in conjunction with calcium disodium EDTA.

Reports have indicated that thiamine therapy is an effective adjunctive treatment with EDTA in cases of acute lead poisoning of cattle.[1275,1307,1308] Administration of 2 mg/kg thiamine daily was more effective than treatment with disodium EDTA (62 mg/kg twice daily for 4 days) or thiamine plus disodium EDTA in inducing remission of clinical signs of experimentally induced lead poisoning.[1309] For clinical treatment of lead poisoning, thiamine dosages of 500 mg for small ruminants and 1 g for cattle weighing 300 kg or 5 mg/kg have been recommended.[1307] Administration of daily doses of thiamine (100 mg/calf/day or 5 mg/kg) has protected experimentally exposed calves from clinical signs of lead poisoning and reduced lead deposition in the soft tissues.[1308,1310,1311] The nature of the protective effects of thiamine is unclear. Apparently, either

lead interferes with thiamine synthesis, or the tissue distribution and deposition of lead are reduced by the formation of rapidly excreted lead-thiamine complexes.

In ruminants, ingested lead is best removed from the digestive tract by means of a rumenotomy.[1275] Magnesium sulfate laxatives are administered concomitantly to form insoluble lead sulfides. Because of the possibility of additional lead absorption from the GI tract, oral administration of chelators is contraindicated.

Patients that respond slowly to chelation and thiamine therapy should be given supportive care. These measures should include provision of 40 to 80 mL free water/kg/day for maintenance, oral hyperalimentation, and administration of diazepam or phenobarbital for convulsions (see Table 35-9).

35.2.39.8

Prevention and Control

Toxic pastures can be made safe by removing contaminated forage. This is best done by cutting, baling, and burying native grasses; burning the stubble; and applying agricultural lime at the rate of 1 ton per acre where the lead concentration of topsoil exceeds 175 ppm.[1266] In the case of negligent poisonings, vigorous attempts at laboratory confirmation of the clinical diagnosis should be made. The source of the lead should be established, and the affected animals should be carefully documented. In the United States, insurance liability responsibilities may be covered under homeowner or farm insurance.

35.2.40

TOXICITY FROM GASOLINE, PETROLEUM DISTILLATES, AND RELATED PRODUCTS

Ingestion of natural gas condensate or petroleum distillates can cause neurologic disease in livestock. Affected animals appear to be anesthetized and fail to respond to auditory or visual stimuli. The clinical signs of petroleum distillate poisoning include depression, ataxia, diarrhea, recumbency, coma, semicoma, absent menace response, decreased palpebral reflex, and muscular hypotonia. Constituents of petroleum and related products cause pathology in many organs, including the lungs, kidney, liver, and digestive tract. Thus a variety of clinical signs, such as dyspnea, coughing, and bloat, may be present in poisoned animals, in addition to neurologic abnormalities.[1312,1313] The feces and digestive tract contents have a strong odor of petroleum or gasoline. Some animals may die suddenly without premonitory signs. Animals in poor condition or suffering from chronic illness are at greatest risk of toxicity.[1314]

Necropsy findings in poisoned animals include diffuse serosal hyperemia of the bowel and forestomachs and diffuse serosal ecchymotic hemorrhages. The lungs are firm and mottled, especially in the middle and cranial lobes. These pulmonary changes may be associated with moderate amounts of serofibrinous pleural exudates. Microscopic changes in poisoned animals include myocardial degeneration and necrosis, enteritis, mild renal tubular degeneration, and granular eosinophilic casts. Affected livers develop periacinar fatty degeneration and periportal infiltrations of lymphocytes and plasma cells.

1035 1036

Gas chromatography of the intestinal contents usually reveals peaks of aromatic hydrocarbons. For identification of the source of hydrocarbons, gas chromatographic profiles of the environmental specimens can be compared to those of the rumen liquor. Several oxidative biochemical activities of circulating neutrophils are reversibly depressed in animals exposed experimentally to crude oil or diesel fuel. This effect is dose dependent and may provide a method for determining exposure to oil and petroleum products and for tracking recovery.[1315]

In early cases of petroleum distillate poisoning, removal of the hydrocarbons by means of a rumenotomy should be considered. Treatment usually is futile when the animal becomes recumbent and unresponsive.[1316]

35.2.41 ETHYLENE GLYCOL TOXICOSIS (ANTIFREEZE POISONING)

Antifreeze poisoning occurs primarily in ruminants.[1317,1318] When ingested, ethylene glycol is enzymatically converted to a number of acidic intermediate compounds, especially glycolic acid, which is further metabolized to oxalic acid. This acid combines with calcium in the kidneys to precipitate as calcium oxalate. Ruminants are thought to be more resistant to the toxic effects of ethylene glycol than monogastric animals because of their ability to metabolize large quantities of oxalate in the rumen. The acute toxic dose of ethylene glycol for adult ruminants ranges from 5 to 10 mL/kg, whereas that for preruminant calves is 2 mL/kg.

Animals that have ingested sufficient amounts of ethylene glycol become ill by 3 to 4 days after ingestion. Clinical signs of ethylene glycol toxicity include blindness, progressive hindlimb ataxia, salivation, depressed sensorium, nystagmus, tonic-clonic seizures, and status epilepticus. Pupillary reflexes usually are intact. Hemolytic anemia and hemoglobinuria occasionally may be seen.[1317] The clinicopathologic changes of ethylene glycol toxicosis include azotemia (448 mg/dL), increased serum creatinine, hypophosphatemia, hypocalcemia, acidosis, hyperosmolality, and increased γ-glutamyl transaminase.

The pathologic lesions include slight swelling of the kidneys and pulmonary edema. Oxalate crystals can be demonstrated by microscopic examination of the kidney tissues using polarized light. Ethylene glycol can be detected in the rumen for at least 4 days after ingestion. Mass spectrometry of body fluids may show increased urinary and ocular fluid concentrations of glycolic acid (4.3 μg/mL and 2.3 μg/mL, respectively).

Treatment with 20% ethanol at a rate of 50 mL/hr has been recommended but is unsuccessful in advanced stages of the disease. Some have suggested that ruminants also be given an oral dose of activated charcoal, but the effect of this treatment on long-term survival is unknown.[1318]

35.2.42 NARDOO FERN POISONING

Sheep that graze extensively on the Nardoo fern *(Marsilea drummondii)* develop a condition that is indistinguishable from polioencephalomalacia (PEM). Death losses of 2200 of 57,000 sheep have been reported.[1319] The clinical signs are indistinguishable from those of PEM. Neuronal necrosis, malacia, perivascular cuffing, vacuolation of the neuropil, vascular dilation and endothelial hypertrophy, and gliosis occur in the central nervous system. The condition responds to a single subcutaneous injection of thiamine (200 mg). The fern is thought to contain a form of thiaminase I.

35.2.43 *HELICHRYSUM ARGYROSPHAERUM* POISONING

Both naturally occurring and experimental poisoning of sheep and cattle in South Africa by plants of the genus *Helichrysum* results in blindness and a variety of CNS signs.[1320,1321] The clinical signs of intoxication include progressive tetraparesis, depression, nystagmus, mydriasis, blindness, intentional head tremor, and star-gazing attitude. Older sheep may develop lens cataracts 2 to 3 months after eating the plants. The case-attack rate ranges from 1% to 29%. Plants are toxic only in the flowering stage. *Helichrysum* species have been shown to

contain substances that bind at the γ-aminobutyric acid (GABA)—benzodiazepine receptor, suggesting a mechanism for toxic effects on the nervous system.[1322]

Pathologic findings include widespread status spongiosus of brain white matter, particularly in subependymal areas and in the cerebellar peduncles and brainstem.[1321] Myelin edema is present in some cases. Edematous swelling of the optic nerve causes compression of the nerve in the optic canal, with secondary damage to nerve axons and myelin. The toxic principle in *Helichrysum* plants also causes a primary retinopathy in some animals.

Other members of the *Helichrysum* genus are being studied for a variety of medicinal properties, including antiviral, antioxidant, antiinflammatory, and free-radical scavenging activities.[1323–1325]

35.2.44 FLATPEA *(LATHYRUS SYLVESTRIS, LATHYRUS COLLIS)* POISONING

Ingestion of flatpea *(Lathyrus sylvestris, Lathyrus collis)* results in a CNS disorder. The condition may be seen by 5 days after consumption of a diet composed of 50% flatpea vines. Toxicosis has been induced in sheep ingesting forage of 35% flatpea vines.[1326] Livestock can develop a tolerance for the plant through rumen microbial detoxification. Nevertheless, acclimatized animals can be rendered susceptible by treatment with monensin or by a change in rumen microflora.[1327]

The toxic constituent of the plant, 2,4-diaminobutyric acid, is known to inhibit ornithine transcarbamylase, an enzyme responsible for urea detoxification. Consequently, the blood ammonia concentration in clinically affected animals ranges from 189 to 263 mmol/mL (normal, 108 to 185 mmol/mL). Diaminobutyric acid also interferes with the uptake of GABA and inhibits GABA transaminase activity.

The clinical signs of flatpea intoxication are depression, muscular tremors, and spasmodic torticollis. Affected animals become recumbent and are reluctant to rise. When stimulated to move, they display circling, head pressing, and odontoprisis. The urine may appear dark brown. The clinical disorder often culminates fatally in a seizure. During the interictal periods the animals may rest, rise, and resume normal behavior and gait. Treatment is empiric and supportive and could include 1 to 2 L of vinegar orally, IV diazepam, and removal from the offending forage.

Lathyrus sylvestris is a leguminous plant with a high protein content that might be an adequate substitute for alfalfa in areas where the latter grows poorly.[1328] *L. sylvestris* harvested in the vegetative state has been fed to lambs in combination with alfalfa and as a sole diet without ill effect.[1329] Similarly, when fed as part of a mixed silage in which the concentration of diaminobutyric acid was approximately 1%, *L. sylvestris* produced an acceptable weight gain in cattle without signs of toxicity.[1330]

35.2.45 LEUKOENCEPHALOMALACIA (MOLDY CORN DISEASE; EQUINE ENCEPHALOMALACIA; PESTA DE CEGARE; PEN YAN DISEASE; MOLDY CORNSTALK DISEASE; BLIND STAGGERS)

35.2.45.1 Definition and Etiology

Leukoencephalomalacia (LEM) is an intoxication of horses caused by ingestion of corn contaminated with the fungus *Fusarium moniliforme*.[1331–1335] Fumonisin toxins (B1, B2, and B3) produced by *F. moniliforme*

interfere with sphingolipid metabolism, disrupting endothelial cell walls and basement membranes.[1336] Although all three substances are toxic, fumonisin B1 is believed to be mainly responsible for LEM.[1337] Outbreaks of multifocal neurologic signs and hepatic disease occur in groups of horses exposed to tainted feedstuffs.

35.2.45.2 Clinical Signs

The clinical signs of LEM occur suddenly. Occasionally, animals die acutely, without other overt signs,[1338] but most horses show a variety of neurologic signs before death. These include somnolence, flaccidity of the facial and pharyngeal muscles, muscle fasciculations over the neck and withers, ataxia, conscious proprioceptive deficits, head pressing, mania, facial desensitization, pharyngeal paralysis, blindness, seizures, and a tendency to circle or lean to one side.[1338,1339] Most animals die while convulsing.[1331] The few horses that recover usually have permanent neurologic dysfunction. Hepatic involvement occurs in many cases, as evidenced by elevated serum liver enzymes, although hepatic failure is uncommon. Signs of liver disease include icterus, petechiation on mucous membranes, and swelling of the muzzle or lips. Gastrointestinal disease caused by fumonisin toxins has been reported and may manifest as signs of colic.

Unique constellations of clinical signs may predominate within any one outbreak of the disease. Fumonisin toxins cause a variety of clinical syndromes in other species, but horses appear to be particularly susceptible and can show signs when exposed to toxin concentrations as low as 5 to 10 ppm, almost 10 times less than the concentration needed to cause mild signs of inappetence and decreased weight gain in cattle.

35.2.45.3 Clinical Pathology and Diagnosis

Fumonisin toxicosis has no unique clinicopathologic findings, therefore antemortem diagnosis relies on recognition of the clinical signs with a history of exposure to moldy corn. Specific changes in the cerebrospinal fluid (CSF) of affected horses have not been reported. Serum liver enzymes (aspartate transaminase [AST], γ-glutamyltransferase [GGT], sorbitol dehydrogenase [SDH]) and bilirubin may be elevated. Nonspecific changes in serum chemistry associated with dehydration (increased hematocrit, prerenal azotemia) and recumbency (elevated serum creatine kinase [CK]) also may be present. Anemia, leukocytosis, and leukopenia all have been reported, but none is a consistent finding.

Differential diagnoses include craniocerebral trauma, the arboviral encephalitides, hepatic encephalopathy, equine protozoal myeloencephalitis, Theiler's disease, and botulism.

35.2.45.4 Epidemiology

Leukoencephalomalacia occurs worldwide.[1333,1340] Corn becomes contaminated during growth rather than in storage, and climatic factors that stress the plants, such as drought, excess moisture, or heat, contribute to the likelihood of mold development. Most cases of equine disease occur during the winter and early spring.[1332,1338] In experimental studies the toxic dose of infected corn ranged from 5 to 15 kg (10 to 30 lb), but the amount of corn required to cause the disease is likely to vary considerably depending on the amount of toxin in the grain.[1334] A direct link between the onset and severity of clinical signs and the dose of toxin has not been established in naturally occurring cases, but experimental data suggest a dose-related effect.[1341] Repeated exposure to the toxin, rather than a single large dose, seems to be associated with the development of clinical signs.[1342] Experimental studies with infected corn demonstrated an onset of clinical signs on the

ninth day after the beginning of the feeding period. Older animals develop clinical signs of LEM more rapidly than younger animals and thus appear to be most susceptible to the effects of the mycotoxin.[1334]

The rates of disease in exposed horses vary widely, from 14% to 100% in some reports.[1343–1346] Ruminants apparently are more resistant than horses to the effects of the neurotoxin, but this is not a complete resistance because camels and water buffalo have died after ingesting toxic corn. Diplodiosis, a similar neuromycotoxicosis of cattle caused by ingestion of *Diplodia maydis,* occurs in Africa; however, the toxicologic relationship between these conditions is unknown.

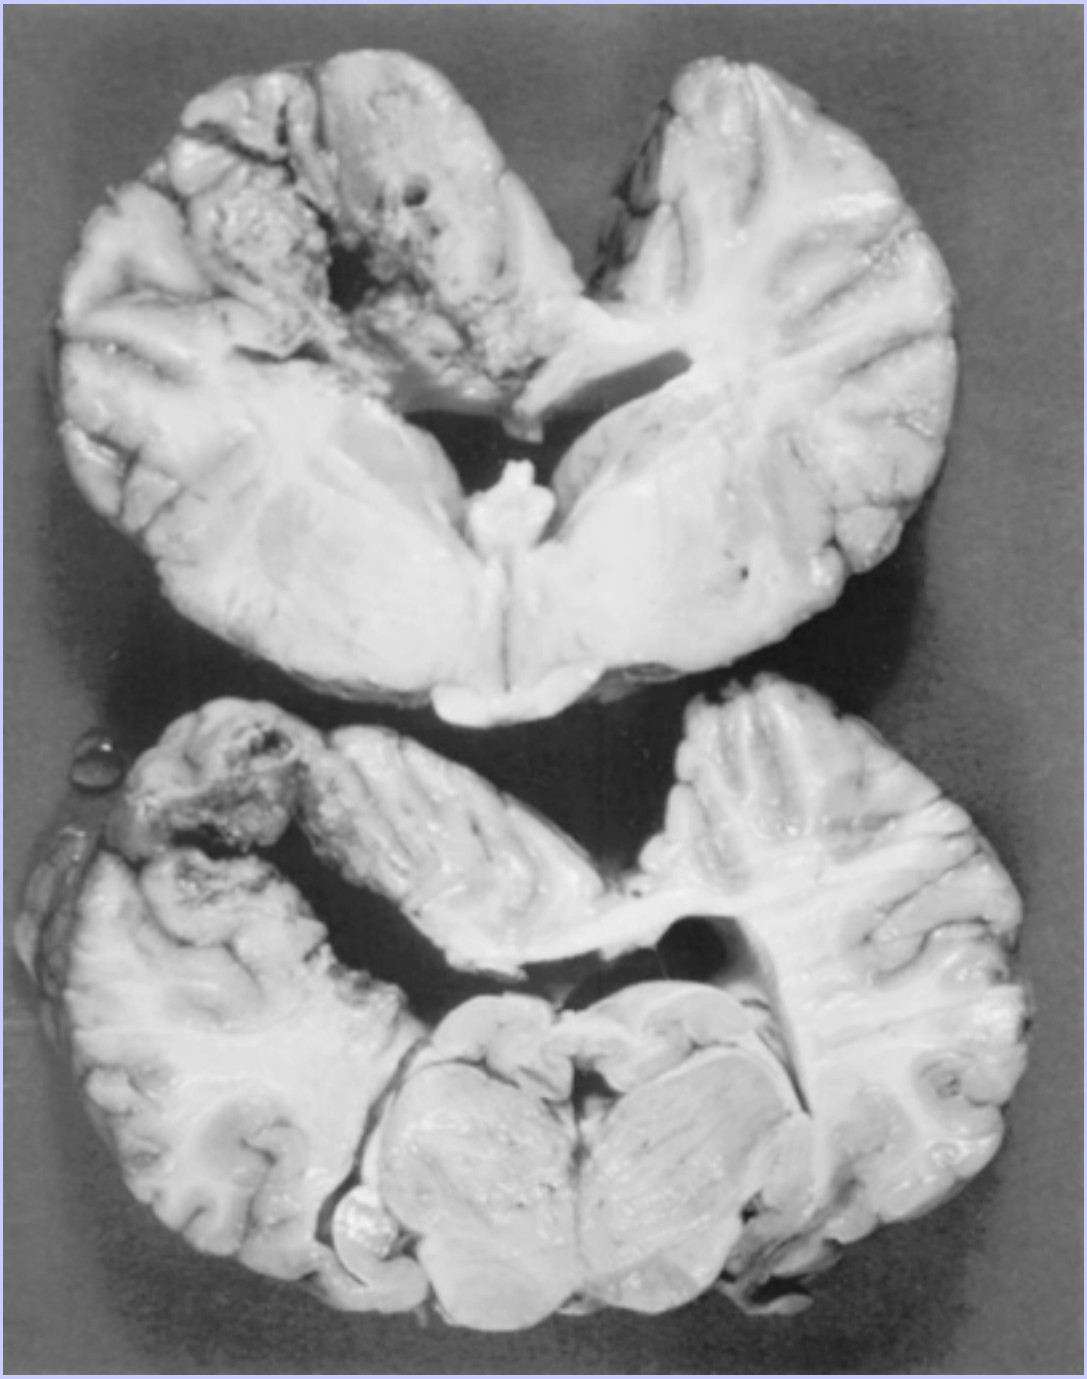
35.2.45.5

Pathology

The major pathologic features in the central nervous system (CNS) result from the vascular damage caused by fumonisin toxins, including liquefactive necrosis and degeneration or malacia of the white matter of one or both cerebral hemispheres.[1347,1348] The size of the lesions may vary from 0.5 cm in diameter to complete necrosis of the entire cerebral cortex.[1331] Flattening of the cortical gyri, enlargement of the cerebral cortex, vascular congestion, cortical softening, yellowish discoloration of the white matter, hemorrhage, and cavitation of the cerebral cortex may be present[1331,1338,1340] (Fig. 35-14). A gelatinous fluid can be seen in many of the cavitary lesions.[1338] Hemorrhage in the CNS also has been reported.[1343] Lesions in the visceral organs, including hepatic congestion, centrilobular hepatic necrosis, hemorrhagic enteritis, and cystitis are found in some horses. The relationship between these lesions in the CNS and those in the liver, urinary bladder, and GI tract is unknown.

1037 1038

Fig. 35-14 Characteristic appearance of a malacic lesion in the brain of a horse that died of moldy corn poisoning. Courtesy Dr. R.H. Whitlock.



35.2.45.6 Treatment

There is no known specific treatment for LEM, but successful treatment of horses was reported using antiinflammatory medications such as dimethyl sulfoxide (DMSO) (1 g/kg given as 10% solution by slow IV infusion once daily for 3 days) or flunixin meglumine (0.25 to 1 mg/kg), as well as antibiotics and supportive care (thiamine, 5 g IV every 12 hours).[1349] In other cases, survivors usually have permanent neurologic dysfunction.

35.2.46 BLUE-GREEN ALGAE TOXICOSIS

35.2.46.1 Definition and Etiology

Ingestion of stagnant pond water containing certain species of blue-green algae may result in a peracute intoxication of livestock. Blue-green algae poisoning is characterized by convulsions, ataxia, bloody diarrhea, and sudden death.[1350–1353] Although often a fatal toxicity, some affected animals can make a full recovery.[1351,1354] The algal toxins have been responsible for high losses of livestock and illness in humans and for deaths of domestic dogs.[1355,1356] The algal toxins may also be responsible for occasional die-offs of fish and aquatic birds. Toxic algal species include *Microcystis aeruginosa, Anabaena flos-aquae, Aphanizomenon flos-aquae, Anacystis cyanea, Gloeotrichia echinulata, Nodularia sphaerocarpa,* and *Oscillatoria agardhii*. Of these, the first three are most toxic.[1357] Blue-green algae poisoning most often results in sudden death. Affected animals rarely move far from the source of the toxin. Some of the algae produce hepatotoxins, and animals develop liver failure, diarrhea, and photosensitivity. The development of toxic stands of blue-green algae requires specific environmental conditions, including a water pH above 6, organic pollution, and a water temperature ranging from 15° C to 30°C (59° F to 86°F).

35.2.46.2 Clinical Signs

Clinical syndromes of blue-green algae poisoning in livestock may be separated into acute and chronic forms. Acutely affected animals may show signs resembling those of milk fever,[1354] including muscle tremors, reluctance to rise or move, ataxia, cold extremities, weak rapid pulse, mydriasis, muscle tremors, salivation, colic, rumen atony, mild bloat, pallor, increased capillary refill time, vomiting, ataxia, conscious proprioceptive deficits, and bloody diarrhea. Some of the toxins are absorbed through the oral mucosa. Consequently, the full range of clinical signs, culminating in death from respiratory arrest, can occur within minutes of ingestion of the toxic water. If clinical signs are seen before death, affected animals tend to be afebrile but have significantly increased pulse and respiratory rates. Many animals die suddenly without premonitory symptoms.[1358,1359] The deaths often occur in the vicinity of the pond, and dead animals may be covered by the green scum.

In the chronic form of blue-green algae intoxication, affected animals show ataxia, depression, anorexia, hemorrhagic diarrhea, icterus, and photosensitization, which occur secondary to hepatic necrosis.[1359] Death from respiratory arrest and circulatory shock may occur within 2 to 72 hours after the toxin is ingested.

35.2.46.3 Clinical Pathology

The diagnosis of blue-green algae poisoning depends on recognition of a relationship between livestock deaths and ingestion of pond water, identification of toxic algae in the pond water, recognition of hepatic disease in chronically affected animals, and elimination of the possibility of similar clinical conditions, such as cyanide or acute poisoning. Diseases that kill animals suddenly should be considered as differential diagnoses (see Chapter 14). Blue-green algae poisoning should be considered whenever a group of cattle simultaneously develop marked massive hepatic necrosis.

The vegetative cells of the algae can be identified by microscopic examination of rumen contents. The intestinal contents should be split. Half the contents should be placed in 10% neutral buffered formalin for microscopic analysis, and the other half should be refrigerated (not frozen) for mouse bioassay tests or chromatographic identification of the toxin using high-performance liquid chromatography (HPLC).[1360] The blood of animals poisoned by microcystin, the toxic principle of *Microcystis aeruginosa,* shows changes characteristic of hepatic necrosis, including increased concentrations of bilirubin, AST, GGT, alkaline phosphatase (ALP), and arginase. The animals may be secondarily hypocalcemic, which complicates the clinical picture.[1354]

35.2.46.4 Pathophysiology

Blue-green algae grow more slowly than other algae in cold water; therefore, highly flushed systems cannot achieve a toxic bloom. The blue-green algae can fix atmospheric nitrogen dissolved in the water, and they have intracellular gas vesicles that accumulate the nitrogen when photosynthesis decreases. If mixing occurs because of the wind, the amount of light reaching the algae decreases because of the turbulence. The buoyancy of the cells increases because of decreased photosynthesis. At night the winds become calmer, and the algae lose their ability to regulate density. The cells float to the surface of the water and form a scum, which is concentrated on the leeward side. For these reasons, poisonings tend to occur in the period of stable weather just after a frontal system has passed.

Direct ingestion of the toxicant is necessary to cause clinical signs. No significant level of toxin was detected in milk of cows fed the toxin experimentally, so calves are not exposed through their dams' milk.[1361]

All species of blue-green algae probably produce toxins, which can be classified into the following three groups:

- *Aphanizomenon, Oscillatoria,* and *Anabaena* species. *Aphanizomenon* produces two alkaloid toxins that have a structure resembling that of saxitoxin, the agent of paralytic shellfish poisoning. Toxins from *Anabaena* species are named anatoxin-a and anatoxin-a(s) and are structural analogs of cocaine. Toxins from *Oscillatoria* species resemble those of *Anabaena;* they can be absorbed unchanged through the mucous membranes and kill by depolarizing blockade of the neuromuscular junction.[1358,1359,1362–1364]

- Peptide hepatotoxins. These substances are produced by strains of *Microcystis, Oscillatoria,* and *Anabaena* algae. Microcystin-LR is the most frequently isolated hepatotoxin.[1365–1369] On a weight basis, this toxin is 20 times more active than cyanide or strychnine. A single intraperitoneal injection of 1 to 2 µg in a mouse is lethal. At least nine structural variants of microcystin have been identified.

These toxins act exert their toxic effects on mitochondria.[1370] The toxins can cross the placenta and cause lesions in the fetus.

- Lipopolysaccharides. These substances may be produced by most species of blue-green algae.

35.2.46.5 Necropsy Findings

The pathologic lesions of blue-green algae poisoning are either severe centrilobular hepatic necrosis in animals that die of the chronic poisoning or generalized petechiation and body cavity effusions in animals that die peracutely.[1358]

35.2.46.6 Epidemiology

Blue-green algae intoxication occurs worldwide and affects mammals, birds, and fish. The bloom is most abundant during the late summer and early autumn when warm, sunny conditions favor algal growth. Growth is most abundant in ponds with an alkaline pH and in high concentrations of nitrogen, phosphates, carbonates, or organic matter. Release of the toxin is associated with death of the algae and production of a “rotting fish” odor. Most poisonings occur on the leeward side of the pond, where the algae are concentrated by the action of the prevailing wind. Ingestion of approximately 1080 to 1500 mL of heavily contaminated water can be fatal for cattle.[1350] Toxicity varies daily and in different parts of the pond or lake.

35.2.46.7 Treatment

Therapy for blue-green algae poisoning is symptomatic and usually unsuccessful. Experimentally poisoned calves have not recovered, even after 30 hours of artificial respiration, although recovery of cows naturally intoxicated has been reported.[1351,1363]

35.2.46.8 Prevention

Methods for control of the disease include restriction of access to infested ponds and treatment of the pond with copper sulfate or algacides.[1352] Prevention of blue-green algae poisoning depends on the proper construction of farm ponds and the prophylactic treatment of the water with bluestone (copper sulfate) to achieve a final concentration ranging from 0.5 to 1.0 ppm in acid water and 1.5 to 2.0 ppm in alkaline water. The bluestone is either dissolved in water and sprayed over the pond or dragged through the pond in a burlap sack in lanes that are 5 to 10 feet apart.[1352] This amounts to 1.22 kg/acre foot in alkaline water. Cattle should be fenced from the pond for several days after the copper sulfate treatment. The treatment should be repeated whenever the toxic bloom recurs. To prevent algal bloom without application of copper sulfate, farm ponds should be constructed so that they are 80 × 20 feet in length and width and 10 feet in depth. Surrounding drainage areas should be fenced from the livestock. Water should be pumped from the pond to the cattle in polyethylene pipes and delivered into raised water troughs. The water for the troughs should be pumped from the center and bottom of the pond.

35.2.47 NITROFURAZONE TOXICOSIS

Nitrofurazone is an antimicrobial that has been fed to cattle for the treatment and control of respiratory or gastrointestinal diseases. Treatment of food-producing animals with the nitrofurans currently is prohibited by the U.S. FDA. Nervous system signs of nitrofurazone toxicosis occur after 1 to 3 weeks of continuous feeding at dosages exceeding 15 to 30 mg/kg.[1371,1372] Lower dosages (7.1 mg/kg) reduce feed intake but do not result in neurologic signs. The nitrofurans inhibit enzymes of the oxidative glycolytic pathways and are thought to interfere with brain metabolism of carbohydrates.

Clinical signs of nitrofurazone toxicosis include hyperirritability, propulsive running, muscular tremors, blindness, convulsions, and death. At lower doses the convulsions may appear intermittently, but as the condition progresses, the signs become continuous.

35.2.48 INTRACAROTID DRUG INJECTION

35.2.48.1 Definition and Etiology

Intracarotid drug injection is common in horses because the jugular vein and the common carotid artery are closely apposed in the caudal third of the neck. The condition is rarely seen in cattle because the omohyoideus muscle lies between the carotid artery and the jugular vein in the posterior part of the neck. Hypertonic or caustic drugs, including phenothiazine tranquilizers, chloramphenicol, chloral hydrate, barbiturate anesthetics, phenylbutazone, calcium gluconate, sodium iodide, and chloramphenicol, cause cortical necrosis when injected into the carotid artery.[1373,1374]

35.2.48.2 Clinical Signs

The onset is peracute. When the drug is injected into the carotid artery, the animal recoils backward and falls over. Some horses strike or rear violently or run wildly without regard to obstructions. Other animals fall down and become comatose without showing severe motor activity. Severely affected animals may die after a variable period, but others regain their footing and recover completely. Residual neurologic deficits may occur in surviving animals. These deficits include contralateral blindness, facial hypalgesia, head tilt (toward the side of the lesion), and a largely contralateral, conscious proprioceptive deficit. If the injection has damaged the ascending vagosympathetic pathways, the animal may display Horner's syndrome, with signs that include ptosis, miosis, and enophthalmos. Horses with Horner's syndrome also sweat profusely over the head and neck of the ipsilateral side, whereas cattle with the syndrome fail to sweat on the planum nasale on the ipsilateral side of the lesion.

35.2.48.3 Pathophysiology

The CNS lesions are caused by vascular endothelial damage. Intracarotid drug injection results in intense vasospasm and profound alterations of the blood-brain barrier (BBB). The vascular damage causes endothelial cell swelling, increased vascular permeability, mural necrosis, hemorrhage, intercellular edema, and thrombosis.[1373]

35.2.48.4 ### Necropsy Findings

Pathologic lesions include diffuse cerebral edema and brain swelling. Microscopic lesions include arteriolar hyalinization, hemorrhage, edema, necrobiosis, and status spongiosus. Vacuolation of the neuropil, perivascular hemorrhage, fibrin, and edema are also seen.

35.2.48.5 ### Treatment

No effective treatment exists for an accidental intracarotid drug injection. Violent horses should be placed in a padded stall, sedated with diazepam, and treated with dexamethasone (1 to 2 mg/kg). Administration of mannitol or other osmotic diuretics should be avoided in the first 24 hours because of active bleeding in the CNS and loss of the BBB. Administration of a hypertonic dehydrating agent at that time may result in distribution of the osmotically active drugs into the CNS parenchyma, resulting in a large increase in intracranial pressure. Although most animals eventually recover from the effects of an intracarotid injection, fatalities have been reported.[1373–1375]

35.2.48.6 ### Prevention

Intracarotid injection of drugs is best prevented by the use of large-bore needles or catheters for intravenous injections. This allows better visualization of pulsating oxygenated blood when the carotid artery has been accidentally punctured. In the horse, venipunctures should be performed in the anterior one third of the jugular furrow because the artery and vein are separated by the omohyoideus muscle in this area. Needles should be inserted into the vein while they are separated from the syringe.

1040

35.2.49 ## COENUROSIS (SHEEP GID; *COENURUS CEREBRALIS* INFESTATION; *TAENIA MULTICEPS* INFESTATION)

35.2.49.1 ### Definition and Etiology

Coenurosis is caused by invasion of the CNS by *Coenurus cerebralis,* the intermediate stage of the tapeworm *Taenia multiceps*. The adult worms live in the intestine of domestic dogs and some wild carnivores, where they shed eggs into the feces. Ruminants eat the eggs from contaminated pastures. The eggs hatch in the small intestine of the ruminant, and the larval stages travel through the blood to the CNS, where they mature into *C. cerebralis*. The life cycle is completed when the ruminant dies and the brain is eaten by a scavenging carnivore. *Coenurus* cysts then develop into sexually mature adults in the bowel of the carnivore host.

Many animals, including sheep, goats, cattle, horses, wild ruminants, and humans, are susceptible to *C. cerebralis* infestation.[1376–1378] Outbreaks of coenurosis may occur in previously uninfected sheep that are suddenly exposed to contaminated fecal matter from carnivores. Cases initially occur as early as 2 weeks after the sheep are exposed and continue for as long as 4 months.

35.2.49.2

Clinical Signs

Signs can occur acutely, during the migratory phase of the larval stage in the intermediate host. Lambs 6 to 8 weeks old are most often affected by this form and develop fever, dullness, and mild neurologic deficits.[1379] Occasionally, acute encephalitis occurs, leading to sudden onset of severe neurologic signs and death within a few days. More frequently, the clinical presentation of coenurosis is that of a space-occupying brain lesion; signs include depression, anorexia, ataxia, unilateral or asymmetric loss of vision, facial hemiplegia, head tilt, circling, high-stepping forelimb gait, and hyperesthesia. When the spinal cord is the site of cyst development, hindlimb ataxia and paresis to paralysis is the main clinical sign.[1380] As the disease progresses, the sheep assume lateral recumbency and become comatose.[1381,1382] In advanced cases the calvarium directly over the parasite enlarges and softens.[1378]

35.2.49.3

Pathophysiology

Lesions of the CNS may result from three separate pathogenic mechanisms. These include encephalitis from invasion of the CNS by large numbers of larvae, hypertensive hydrocephalus resulting from interference with CSF drainage, and development of large cerebral cysts that increase intracranial pressure. Full development of the *Coenurus* cyst requires 6 to 7 months. Mature cysts may reach 5 cm in diameter and displace the bones of the calvarium.

35.2.49.4

Necropsy Findings

In the acute form of coenurosis, the main finding is coagulation necrosis and inflammation associated with the pathway of the larval form as it migrates through the CNS.[1383] This may be visible grossly as yellow to red tracks through the brain parenchyma. Coagulation necrosis and surrounding inflammatory cells, such as degenerate granulocytes, macrophages, and histiocytes, are found microscopically. The mature cysts, up to 7 cm in diameter, are thin walled and contain clear fluid or, occasionally, purulent fluid. Protoscolices, up to many hundreds, can be visualized microscopically within the cysts, which are surrounded by severe and mainly nonsuppurative inflammation. The cysts deform and compress the underlying brain tissue.

35.2.49.5

Diagnosis

The combination of a characteristic clinical syndrome and location in an endemic area supports a presumptive diagnosis. Radiographs in the lateral and posteroanterior planes may detect radiolucent areas in the calvarium. The optimum diagnostic views in the posteroanterior projection occur whenever the base of the nose is level with the upper margin of the orbit. Computed tomography (CT) effectively demonstrates the presence of cysts but rarely is practicable in large animal species.[1384]

35.2.49.6

Treatment

Praziquantel,* 50 to 100 mg/kg orally daily for 3 to 5 days, is effective for the treatment of coenurosis in sheep that do not yet have neurologic signs.[1380,1385] Concomitant administration of a nonsteroidal antiinflammatory drug (NSAID) or dexamethasone may enhance the posttreatment survival rate.

The cyst can also be removed surgically,[1386] with success rates as high as 90% reported.[1387] A craniotomy is performed over the site of the cyst. Approximately 70% of the cysts are located extradurally and can be removed easily with minimal dissection. The other cysts are located on the surface of the pia arachnoid, in which case the dura mater is incised. The cyst usually bulges from under the incised dura and can be removed. When the cyst is located in the cerebral cortex, ultrasound probes placed on the surface of the brain may be used to locate the pocket of fluid.[1388–1390]

* Droncit, Miles Laboratories, Shawnee, KS.

35.2.49.7 Prevention

In endemic areas the carcasses of affected animals should not be fed to dogs, and dogs in endemic areas should be treated repeatedly with a vermifuge to minimize the possibility of pasture contamination. Appropriate management practices have virtually eliminated this disease from North American sheep flocks. Lyophilized antigens from in vitro—cultured larvae have protected sheep; however, this preparation is not commercially available.

35.2.50 CEROID LIPOFUSCINOSIS

35.2.50.1 Definition and Etiology

Ceroid lipofuscinosis is a lysosomal storage disease that has been reported in South Hampshire, Swedish Landrace, and Rambouillet sheep, Nubian goats, Devon cattle, and horses.[1391–1396] The disease is known to be inherited as an autosomal recessive trait in many cases[1397] and is believed to be so in others.[1396] It is characterized by the intracellular accumulation of abnormal autofluorescent lipopigments in lysosomes of neurons and other cells throughout the body. The storage material has been shown to consist predominantly of the subunit *c* of mitochondrial *c* synthase.[1398,1399] The mechanism of neuronal dysfunction is hypothesized to be mediated by N-methyl-D-aspartate (NMDA) receptor excitotoxicity.[1400] Affected animals display progressive ataxia and postural abnormalities, blindness due to retinal involvement in many cases, sensory depression, and terminally, coma. Lesions seen on CT scans include enlargement of the lateral ventricles and reduced thickness of the cerebral cortex.[1401]

Gross pathologic lesions in the CNS may include moderate enlargement of the lateral ventricles, flattening of cerebral gyri, and a yellow to brown discoloration of the brain parenchyma. Accumulation of protein storage material in neuronal lysosomes is evident on microscopic examination and is accompanied by neuronal necrosis and astrocytosis, which may be severe. The lesions sometimes have a lamellar appearance.[1400] The disease is ultimately fatal, and no practical method of treatment is currently available.

35.3 CITRULLINEMIA

Citrullinemia is a rare genetic defect of Holstein calves that has been reported in Australasia, Europe, and India.[1402–1404] The genetic defect has been found in one carrier bull in the United States.[1405] The mutation responsible has been traced to offspring of a North American sire named Greyview Crisscross and his son Linmack Kriss

King.[1406] Approximately 8% of all bulls used for artificial insemination in Australia are heterozygous for the gene, but the gene prevalence appears to be much lower in the United States.[1405,1407]

Citrullinemia is caused by a defect of argininosuccinate synthetase, an enzyme that processes citrulline in the pathway for the formation of urea. The condition is fatal. Affected calves are normal at birth but become clinically depressed by 24 hours after birth. By 2 to 3 days after birth, affected calves show head pressing, drooling of saliva, bellowing, muzzle twitching, tongue protrusion, and odontoprisis. Convulsions are first seen at 1 to 4 days of age, and death rapidly follows.

The diagnosis may be made by observing an increased concentration of citrulline in the plasma. The concentration of citrulline in normal calves is 0.16 mM and in affected calves is greater than 1.5 mM by the third day after birth. The plasma arginine concentration is decreased to less than 0.02 mM at death.[1408] There is a marked hyperammonemia because of the inactivity of the hepatic ornithine-citrulline cycle. The brain concentrations of the transmitter amino acids glutamate, aspartate, and GABA are decreased. Affected calves also have a reduced affinity of postsynaptic glutamate NMDA receptors in the brain.[1409] The genetic deficit has been traced to the insertion of a chain termination codon for arginine in the argininosuccinate synthetase genome, which causes a complete loss of enzymatic activity. A PCR test for detection of heterozygotes has been developed.[1407] Microscopic brain alterations include astroglial edema and mild to severe spongiform changes in the deep laminae of the cerebral cortex.[1410]

35.4 BRAIN TUMORS

Nervous system tumors of ruminants include medulloblastoma, ependymoblastoma, neurofibrosarcoma, angioblastoma, meningioma, meningeal hemangioma, neurofibroma, schwannoma, choroid plexus papilloma, pituitary adenocarcinoma, primitive neurectodermal tumor, and reticulosis.[1411–1415] Central nervous system (CNS) tumors of horses include pituitary adenomas, microgliomas, medulloepithelioma, choroid plexus papilloma, ependymoma, neurofibroma, meningioma, meningeal carcinoma, and reticulosis.[1411,1416–1420] Secondary tumors that invade the CNS include melanoma, lymphosarcoma, adenocarcinoma, squamous cell carcinoma, hemangiosarcoma, and osteoma.[1411,1420–1424] Of these, lymphosarcoma is most often encountered.[1425–1427] Metastatic invasion to the CNS occurs either by vascular routes or by extension along the peripheral nerve rootlets.[1428] Local extension from adjacent tissue, such as the paranasal sinuses, also can occur.[1421]

Clinical signs of BRAIN TUMORS vary with the location and include abnormalities of gait (ataxia, paresis, hypometria/hypermetria), seizures, altered mentation (especially dullness), facial paresis or paralysis, facial anesthesia or analgesia, dysphagia, head tilt, strabismus, nystagmus, and loss of the menace reflex.[1421,1428–1430] Migration of facial tumors (squamous cell carcinomas) into the cranial vault through the cranial nerve foramina may also result in facial swelling, exophthalmos, Horner's syndrome, or asymmetric airflow through the nares.[1427] Pituitary adenomas of aged horses (see Chapter 41) rarely cause neurologic disease, but they secrete melanocyte-stimulating hormone, which stimulates the adrenal cortex and causes Cushing's disease. Some tumors are discovered as incidental findings at necropsy.

Antemortem diagnostic tests include radiographs of the skull (for tumors that spread locally and some metastatic tumors), and electroencephalography (EEG) to elucidate brain dysfunction.[1421] Where available, CT or MRI can greatly facilitate diagnosis, but limited availability and considerations of cost restrict their use in most cases.[1428,1430–1432]

Treatment of BRAIN TUMORS in horses and livestock is generally not feasible because of limitations of cost, nursing care challenges after craniotomy, lack of access for large animals to radiation therapy, and considerations of safety for personnel handling animals with significant neurologic deficits. Palliative treatment, such as corticosteroids, may reduce clinical signs temporarily in some animals. Euthanasia is the choice for most large animals with BRAIN TUMORS.

35.5 CHOLESTEROL GRANULOMAS

Cholesteatomas are common lesions in the brains of older horses and frequently are incidental findings at necropsy. Cholesteatomas usually are found in the lateral ventricles.[1433] They may form secondary to chronic hemorrhage into the choroid plexuses, but their exact pathogenesis is unknown. Clinical signs of cerebral dysfunction, such as seizures, result only when the masses grow large enough either to obstruct CSF flow from the lateral ventricles or to attenuate the surrounding neuropil directly. Antemortem diagnosis of cholesteatomas in horses can be done by CT scanning of the brain.[1434] Cholesteatomas appear grossly as brownish nodular thickenings in the choroid plexuses or less often as large masses filling the ventricle. Light microscopy reveals abundant cholesterol crystals interspersed with empty clefts, hemosiderin, and an inflammatory reaction consisting of both macrophages and giant cells. There is no specific treatment for cholesteatomas, and relief of clinical signs should be symptomatic, including anticonvulsants as appropriate.

35.6 EPILEPSY

GEORGE M. STRAIN

MARY O. SMITH

LISLE W. GEORGE

Epilepsy is a condition of recurrent seizures not attributable to other neurologic or metabolic disorders.[1435] A seizure (ictus) may be *generalized,* involving the entire cortex and accompanied by loss of consciousness, or *partial* (focal), involving a limited cortical region with no loss of conscious. Partial seizures may in turn become generalized. Seizures may result from trauma, infection, tumors, electrolyte disturbances, or cerebral swelling. Some seizures are idiopathic. Seizures may be preceded by a prodromal aura, usually consisting of a stereotypic sensory disturbance and followed by a postictal depression of variable duration. Seizures in very young or old animals frequently are not of epileptic origin.

Seizure activity results from the synchronization of large aggregates of neurons that are driven, at least in the case of partial seizures, by abnormal epileptic neurons in a seizure focus that recruit increasing numbers of connected neurons.[1436] Generalized epileptic seizure activity may result from subcortical pacing neurons acting through the excitatory amino acid system.[1437] These neurons probably depend heavily on aspartate and glutamate for facilitation.[1438]

Microscopic abnormalities of the brain may be detectable in focal epilepsies but usually are not in generalized epilepsies. Hippocampal degeneration is a well-recognized pathologic change in humans with some forms of epilepsy and has been described in a single cow with seizures. It was not clear in this report, however, whether the hippocampal changes were the cause or the consequence of the seizures.[1439]

Status epilepticus, a condition of repetitive seizures with little or no intervening recovery that requires immediate emergency treatment, may be the first detected clinical manifestation of epilepsy. Status epilepticus may result if antiepileptic medication is abruptly discontinued.

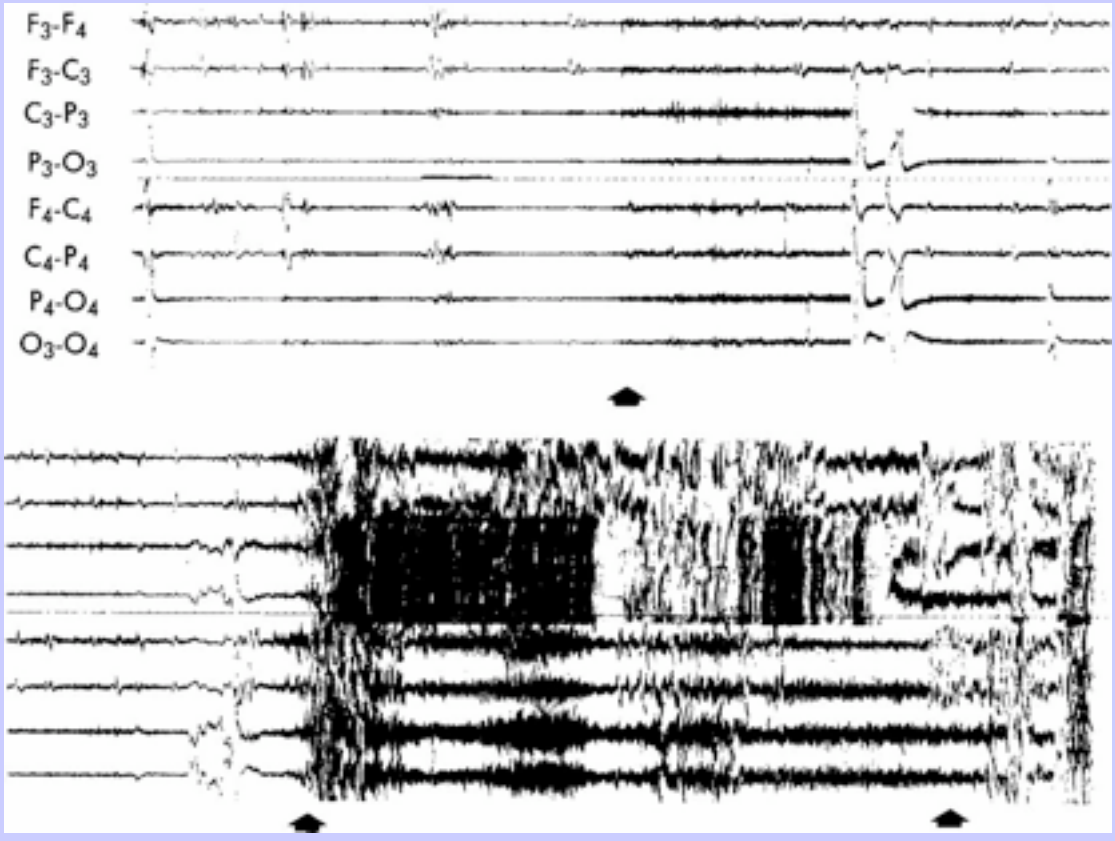
35.6.1 Clinical Signs

Generalized seizures may consist of muscle contractions that are tonic, clonic, or alternating between tonic and clonic. Affected animals may fall and display various autonomic signs, such as salivation, urination, and defecation. During the seizure there may be dorsiflexion of the head and neck and rotation of the eyes. Postictal depression may last minutes to days. Blindness lasting minutes to weeks may be present postictally.[1440] Partial seizures may consist of tonic or clonic contractions of isolated muscle groups without loss of consciousness. Seizure disorders have been described in Romagnola,[1441] Swedish Red,[1442] Brown Swiss[1443] Hereford,[1444] Angus,[1445] Brahman,[1446] and crossbred[1447] cattle. A recent study in Angus cattle suggests that the previously described epilepsy may, in fact, be a cerebellar disease, with episodes of severe cerebellar dysfunction, rather than a true seizure disorder of cerebral origin (see also Bovine Familial Convulsions and Ataxia).[1448] Attacks in a 6-month-old Brown Swiss bull were prompted by undue excitement and declined in number with age.[1449] Young progeny exhibited similar attacks, suggesting that the trait was transmitted as an autosomal dominant genetic character.

Epilepsy has been poorly documented in horses but occurs in Arabians and in some ponies.[1450] There is anecdotal evidence of the existence of the condition in Paso Fino horses of the western United States. A condition known as “benign epilepsy” is seen in foals of many breeds, especially Arabians, but unlike true epilepsy, is usually outgrown. The condition in Arabians is termed “juvenile idiopathic epilepsy.” It occurs in animals of Egyptian lineage, is responsive to antiepileptic drugs (AEDs), and usually resolves by 1 to 2 years of age.[1440] Idiopathic epilepsy in mares has been associated with elevated levels of estrogen.[1451]

An epileptic condition in an 8-year-old Hereford cow has been described.[1444] The seizures began at 6½ years of age. Tonic-clonic convulsions could be elicited by administration of pentylenetetrazol at doses of 4 mg/kg, which was well below the convulsant dose for normal animals. EEG showed high-frequency spike bursts, spike and wave, and polyspike and sinusoidal wave abnormalities (Fig. 35-15). No microscopic abnormality could be found in the CNS of the affected animal. Partial epilepsy has been described in a 5-year-old Nubian goat with a 3½-year history of episodic convulsions. Between episodes the goat appeared to be healthy. The seizures appeared more often at times of peak endogenous plasma estrogen concentrations and could be induced by administration of ketamine. The clinical signs included repetitive tremors of the forelimbs and hindlimbs, head tremors, and mastication without loss of consciousness. The postictal depression lasted for several hours.[1452]

Fig. 35-15 Electroencephalographic (EEG) recording of a tonic-clonic seizure in an epileptic cow elicited by injection of pentylenetetrazol (6 mg/kg IV, marker on time channel). High-frequency EEG changes began at the *first arrow*, the convulsion began at the *second arrow*, and vocalization began at the *third arrow*. Electrodes: left and right frontal (F_3, F_4), central (C_3, C_4), parietal (P_3, P_4), and occipital cortex (O_3-O_4). Calibration: 10 sec and 1 mV; recording bandwidth: 1 to 75 Hz. From Strain GM, Olcott BM, Turk MAM: *J Am Vet Med Assoc* 191:833, 1987.



The EEG evaluation of seizure disorders may be performed using evocative drug challenges with pentylenetetrazol, ketamine, or other seizure-inducing agents and established techniques, but care must be taken to prevent injury to the animal. Although EEG may be of some value in investigation of epilepsy and other brain disorders,[1453] the need for sedation or anesthesia in large animals, combined with the paucity of data available for comparison, limits its usefulness.

Because of the rarity of epilepsy in large animals, specific drug therapies have not been established; however, Table 35-9 presents several drugs that could be administered. These drugs usually are highly protein bound in plasma and can be displaced or functionally altered by other drugs, including tetracycline and chloramphenicol. Because of these potential interactions, these agents should not be used concomitantly with the anticonvulsants.

All anticonvulsant treatments are begun at a low dose, which is increased daily or every second or third day until the seizures have been controlled. If seizures cannot be controlled without causing depression or ataxia, a second anticonvulsant is added. The dose of the second drug is gradually increased until the seizures stop. This combination treatment is continued for 2 to 4 weeks. Thereafter, the first anticonvulsant is tapered until it is discontinued. If seizures reappear, the dose of this drug is increased until they disappear again. After 1 month the trough blood concentration of all anticonvulsants is monitored. Therapeutic trough concentration of phenobarbital is 15 to 40 µg/mL of plasma and for diphenylhydantoin 5 to 20 µg/mL. Any attempt to withdraw anticonvulsant therapy should be made gradually, because rebound seizures may occur with too rapid withdrawal. Dosage recommendations have been established for potassium bromide in horses.[1454] A loading dose of 120 mg/kg daily for 5 days, followed by 90 mg/kg once daily, results in serum concentrations in the range found to be effective for seizure control in other species. However, the efficacy of potassium bromide for seizure control in large animals has yet to be established.

1042
1043

In many animals, epilepsy may be incurable because of its genetic basis. In these cases, treatment is rarely indicated. Horses with epilepsy should not be ridden or used for sporting purposes. Specific methods of control, other than breeding selection against affected animals, are unavailable.

Mares with estral-related seizures may be treated with an ovariectomy. All ruminants experiencing seizures should also immediately be treated with thiamine (10 to 20 mg/kg IM or SC three times daily, or diluted in 5% dextrose or isotonic fluid and given slowly IV) in case the seizural problem is caused by polioencephalomalacia (see previous discussion). The plasma sodium, magnesium, potassium, and calcium levels should be measured in all animals experiencing seizures of unknown origin. Infrequent seizures generally do not justify anticonvulsant treatment, and economic considerations often limit the amount of drug therapy possible. Status epilepticus can be treated with IV diazepam in 5-mg doses until the seizures are controlled or by titrated doses of phenobarbital or pentobarbital.

35.7 NARCOLEPSY AND CATAPLEXY

GEORGE M. STRAIN

MARY SMITH

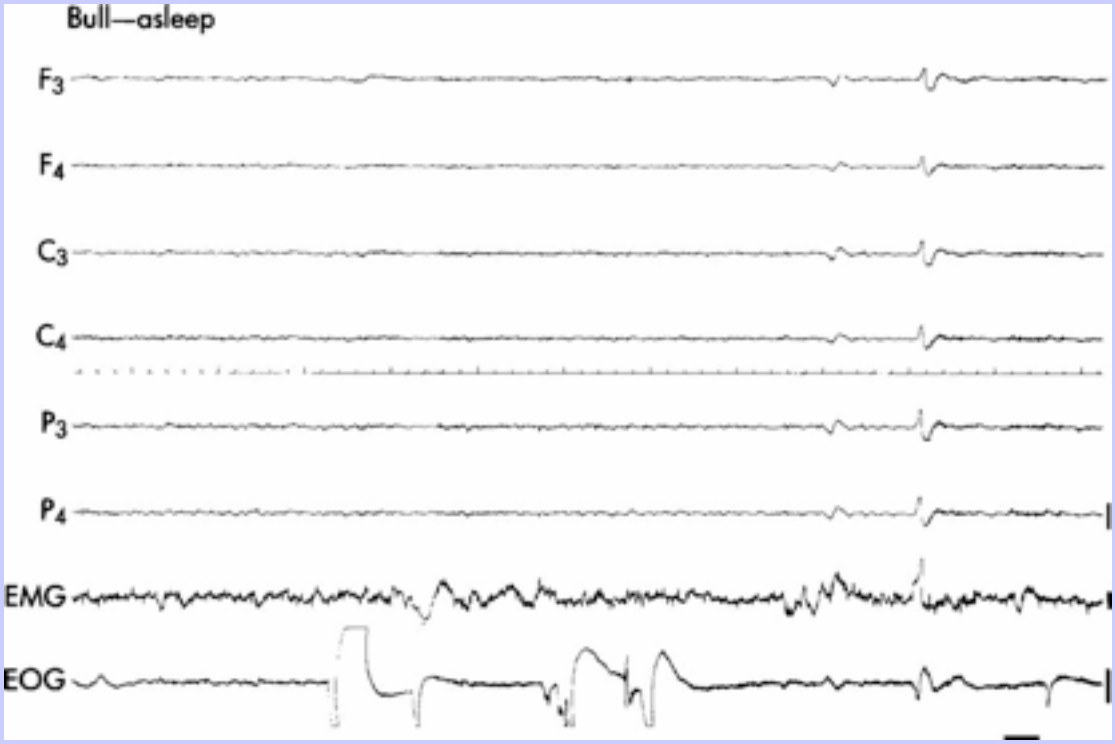
LISLE W. GEORGE

35.7.1 Definition and Etiology

Narcolepsy is a CNS disorder characterized by excessive daytime sleepiness, episodes of muscular weakness (cataplexy), and rapid eye movement (REM)–onset sleep.[1455–1457] Narcoleptic attacks differ from convulsions in that they do not involve tonic-clonic muscular activity.[1455] *Cataplexy,* a sudden episode of paralysis of the voluntary muscles, frequently is induced by stimulation of the patient and can range from atonic, areflexic paralysis of all nonrespiratory muscles to weakness of facial neck and forelimb muscles. Episodes of cataplexy last seconds to minutes. Environmental factors that can stimulate cataplectic attacks include active restraint,

feeding, or changing the stall environment, grooming, or saddling horses in preparation for work.[1455,1458–1460] Excessive daytime sleepiness and REM-onset sleep are difficult to document in large animals, so cataplexy is the most frequently recognized manifestation of sleep disorder in these species.[1461] The disorder is considered an intrusion of aspects of REM sleep into the waking stage, especially the active descending paralysis of skeletal muscle. This intrusion results in indistinct boundaries between wakefulness and REM and non-REM sleep. Cataplectic attacks result from sequential activation of pontine α_1-adrenergic and muscarinic cholinergic systems. The numbers of muscarinic and dopaminergic receptors also are increased.[1456,1462]

Fig. 35-16 Electrophysiologic examination of a narcoleptic Brahman bull. The electroencephalogram shows low-voltage, high-frequency waves in all leads (i.e., left and right frontal [F_3, F_4], central [C_3, C_4], and parietal [P_3, P_4]). The electrooculogram *(EOG)* shows bursts of activity characteristic of rapid eye movement (REM) sleep, and the electromyogram *(EMG)* reflects data from extrinsic ocular muscles.



Attacks of narcolepsy and cataplexy are considered a paradoxic form of sleep because the EEG is characteristic of an alert, awake animal, but the REM is characteristic of deep sleep.[1455] Both neonatal-onset and adult-onset syndromes have been described in horses.[1463] Narcolepsy has been reported in quarter horses, a Shetland pony, thoroughbreds, Morgans, Paint horses, Arabians, Appaloosas, standardbreds, Welsh ponies, Suffolk sheep, Spanish fighting bulls, a Guernsey bull, and a Brahman bull.[1459,1464–1468] A familial occurrence has been reported in American miniature horses.[1469]

35.7.2 Clinical Signs

The clinical signs of narcolepsy include staggering, drooped head, kneeling posture, flaccidity of the lips, closure of the eyes, loss of the menace reflex, stertorous breathing, and proprioceptive deficits. During severe narcoleptic attacks the animal assumes lateral recumbency and appears comatose. The sensorium returns to normal after a time. In the periods between attacks, the patient appears normal.

The EEG changes of narcolepsy and cataplexy have been reported in cattle.[1464] The waveforms vary between low-voltage high-frequency (LVHF) and high-voltage low-frequency (HVLF) patterns, with LVHF corresponding to the actual period of narcoleptic attack (Fig. 35-16). The normal EEG sleep patterns of the horse are usually unavailable, so the technique has limited application for diagnosis of the condition in equine species.

Cataplexy can be induced by IV administration of centrally acting cholinomimetics such as physostigmine salicylate (0.05 to 0.1 mg/kg) or α_1-adrenergic blockers such as prazocin (0.02 to 0.06 mg/kg), but attacks cannot be evoked in all animals. Signs can be reversed for several hours by antimuscarinic drugs such as atropine sulfate (0.02 to 0.1 mg/kg IV once for acute signs). Diagnostic drugs must be used with caution because of possibly inducing colic, especially in horses. Pathologic lesions have not been reported in narcolepsy of large animals. In humans, narcolepsy can be caused by lesions in the rostral brainstem.[1455]

35.7.3 Treatment and Prevention

The tricyclic antidepressant imipramine can be used to treat narcolepsy or cataplexy. Lifelong treatment is required, which must be considered when deciding whether to treat affected large animals. Side effects of imipramine in horses can be serious, including tachycardia, muscle fasciculations, sensitivity to noise, and hemolysis.[1470] Such side effects can occur even when the blood level of imipramine is below the therapeutic range. This drug must be used with caution, and oral dosage in horses should not exceed 2 mg/kg; lower doses should be used when possible.[1457] Results of oral imipramine therapy are inconsistent[1457]; duration of effect is about 5 hours.

35.8 HEAD SHAKING IN HORSES

JOHN E. MADIGAN

Head shaking in the horse is a well-recognized problem that shows no predilection for age, breed, or gender.[1471–1482] Some horses head-shake at rest, whereas most manifest head shaking shortly after the onset of exercise. Head shaking may be vertical, horizontal, or both and often is accompanied by agitation. Suggested causes have included middle ear disorders, ear mites, *Trombicula autumnalis* (harvest mite) larval infestation, cranial nerve abnormalities, ocular disease, guttural pouch mycosis, dental abnormalities, maxillary sinus mass, and allergic vasomotor rhinitis. Finding a specific cause has been difficult, with most cases termed “idiopathic” head shaking. The disorder can occur at any time, but a spring and early-summer pattern is typically reported, although some cases start in the fall and winter.[1480] The research group at University of California, Davis, suggests that neuropharmacologic alterations associated with photoperiod mechanisms, leading to optic trigeminal summation (similar to photic sneezing in humans), may explain the spring onset of head shaking. In many horses, sneezing,

snorting, and nose rubbing accompanies head shaking. Most horses continue head shaking for many years, experience periods of remission, and often resume head shaking at the same time each year.

Examination of horses with head shaking includes a complete physical examination; ophthalmic, otoscopic, neurologic, and dental examinations; endoscopic examination of nasal passages, pharynx, and guttural pouches; radiography of the skull, and a complete blood count and chemistry panel. No abnormalities are usually noted in these examinations.[1483]

Intraorbital neurectomy eliminated head shaking in three to seven horses in one study.[1484] These results would seem to support that some cases of head shaking are caused by a tingling (or other uncomfortable sensation) in the muzzle area. It is postulated that light may play a role in stimulating the response, and that exercise may lower the threshold for onset in some horses.[1483] It is important to note that infraorbital neurectomy has several complications and is not indicated for the treatment of head shaking. The infraorbital branch of the trigeminal nerve is just one branch from that nerve, and it is believed the problem may reside higher up, at the trigeminal ganglia area.

The etiology of head shaking usually is not known. Most horses show no physical abnormalities on comprehensive physical examination, and no lesions have been seen at necropsy. The symptoms in these horses may best be explained by the presence of neuropathic pain involving the trigeminal nerve. Neuropathic pain is a burning, tingling, itching, or electric-like pain that can be intermittent or continuous. Symptoms include sharp, quick movements of the head; occasional striking at the face with a front hoof; excessive snorting and rubbing of the head on objects; carrying the head very low during exercise; and dragging the nose in the dirt. These behaviors could be manifestations of neuropathic pain. The cause of the assumed dysfunction of the trigeminal nerve is not known. The average age of onset of head shaking is 9 years, and most affected horses are geldings, although about 10% to 20% are mares. Often a period of inactivity precedes the onset of head shaking, which can occur quite abruptly.[1485]

Cyproheptadine, 0.3 mg/kg orally twice daily, has been used with some success for idiopathic head shaking.[1483] Cyproheptadine, a type I histamine and serotonergic (5-hydroxytryptamine) blocking agent, was chosen for treating head shaking in horses because of serotonin's role in pain sensations in humans,[1484] and because of photoperiod-induced increases in serotonin in the CNS in the spring. Side effects are few, but mild colic and lethargy have been reported. The drug cannot be used in show or performance horses because it is not an approved medication. Cyproheptadine appears to be effective only when the horse has an adequate blood level of the drug; therefore, it often is not possible to treat a horse and then withdraw the medication before a show and have the head shaking controlled during the event.

Other medications (e.g., corticosteroids, antihistamines, NSAIDs), chiropractic therapy, and acupuncture have not been successful. A few horses respond to a heavy hair net or a dangling device that makes contact with the nose area or upper forehead (Fig. 35-17). This type of contact may prevent the nerve from "firing," similar to blocking a sneeze by placing a finger under the nose and applying pressure. In a review of therapies for head shaking in horses, a nose net device was reported to be successful in approximately 30% of cases.[1486] Box 35-2 lists other treatments used by the author.

Fig. 35-17 Head shake device.

35.8.1

Box 35-2 Treatments and Medications for Horses with Head Shaking*

35.8.1.1

PHYSICAL METHODS

If light is a trigger, consider having the horse wear an ultraviolet (UV) light–blocking sun shade–type fly mask from Guardian Mask, San Diego (http://www.horsemask.com/Main.html).

If the horse is only bothered during exercise, use nose net or other device that attaches to or dangles from over the nostril and muzzle area (e.g., German dangling device); in one stuidy, 30% of head shakers respond.[1486]

The ear covering and forehead "dangling" material.

35.8.1.2

DRUGS TO CONTROL NEUROPATHIC PAIN

Cyproheptidine, 0.3 mg/kg twice daily orally.

Carbamazepine, 1 to 4 g either twice daily or four times daily alone or in combination with cyproheptidine.

Hydroxyzine (Atarax), 400 mg twice daily orally.

Fluphenazine (Repositol), 2 mL IM per horse. Repeat as needed every month or sometimes every 4 months. Use only unopened; if opened, can use refrigerated drug with no discoloration.

Clonidine, 0.0025 mg/kg (0.3-mg tablets); give 4 to 6 tablets orally twice daily to a 500-kg horse.

Phenobarbital, 97.2 mg/tablet; give 16 tablets orally twice daily to 500-kg horse.

35.8.1.3

OTHER TREATMENTS

Lower protein in diet to about 8%. Allow mild weight loss and continue exercise.

Alteration in photoperiod for seasonal head shakers that begin in spring and stop in late fall or winter. Give 12 to 15 mg melatonin orally starting November 1 every day at 5PM. Can try starting in midseason, but not as effective. This resets seasonal clock. Give this dose year-round. Horse may not shed and may need body clipping.

35.8.1.3.1 Combination

Cyproheptidine, standard dose.

Add magnesium supplement: Quiessence (double dose daily).

Spirulina wafers orally.

35.8.1.3.2 Magnesium

Magnesium is an electrolyte that calms nerves by increasing the stimuli needed for depolarization. Supplementing the diet with magnesium may help decrease the stimulation of the trigeminal nerve. One commercial formulation of magnesium, Quiessence, contains 5 g of magnesium per ounce. Feed 2 oz once daily and increase to 4 oz once daily if there is no improvement in the head shaking. Quiessence is available online (http://www.foxdenequine.com/quies.htm).

Have the veterinarian measure the horse's serum magnesium level in about 2 weeks and check it once monthly to ensure it is not high.

35.8.1.3.3 Spirulina

Spirulina is another supplement that may help decrease stimulation of the trigeminal nerve. Administer dose according to the label on the bottle. Spirulina is available online (http://www.springtimeinc.com/ShowView/product/112/1).

35.8.1.3.4 Melatonin

Give 15 mg (average horse) or 18 mg (larger horse) of melatonin orally (five or six 3-mg tablets) every day at 5 PM. Vitaminshoppe is one source for melatonin (http://www.vitaminshoppe.com). Twin Labs is a health food or supermarket brand of melatonin that has good bioavailability. This switches the horse's photoperiod back to winter and sometimes stops the head shaking that starts in the spring.

* There are no clinical controlled trails for these treatment options at this time. None of these suggestions are specific recommendations for an individual horse. Some clients have used these treatments and medications with some degree of success for horses with head shaking. All medications have potential side effects. Owners should always consult directly with their veterinarian before giving any medications to their horse.

35.9 DISEASES PRESENTING PRINCIPALLY WITH BRAINSTEM AND CRANIAL NERVE DYSFUNCTION

LISLE W. GEORGE

35.10 LISTERIOSIS (CIRCLING DISEASE; SILAGE DISEASE; *LISTERIA MONOCYTOGENES* INFECTION)

35.10.1 Definition and Etiology

Listeriosis is an acute meningoencephalitis caused by the gram-positive bacterium *Listeria monocytogenes*. The disease has a worldwide distribution but occurs most often in temperate climates. Listeriosis typically affects ruminants, fowl, and humans but is rare in horses. The prevalence of listeric meningoencephalitis in infected herds does not usually exceed 1% of the adult animals at risk.[1487]

Clinical forms of listeriosis include septicemia of neonates, abortion, neonatal death, ophthalmitis, septicemia and diarrhea of ewes, and neurologic disease.[1488] Usually, only one clinical form is recognized during an outbreak, and only one serovar can be isolated from the clinically affected animals. Neurologic listeriosis may manifest as a multifocal brainstem disorder, as a diffuse meningoencephalitis, or as a spinal cord myelitis. The condition usually affects individual animals but occasionally can affect several members of a herd.[1489] Asymptomatic intramammary infections apparently occur and may be responsible for outbreaks of listeriosis in humans. Repeated intramammary inoculation of 10^6 to 10^7 colony-forming units (CFUs) of *L. monocytogenes* into cattle resulted in 500 to 50,000 CFUs of *Listeria* in the milk for as long as 12 months.[1490]

35.10.2 Clinical Signs

The neurologic signs of listeriosis in adults reflect dysfunction of the caudal brainstem, cerebellar peduncles, or spinal cord.[1491] Signs common to most *Listeria* infections of the central nervous system (CNS) include fever, anorexia, depression, conscious proprioceptive deficits, head pressing, and centrally located cranial nerve deficiencies. Depressed consciousness is the result of lesions of the reticular activating system. Conscious proprioceptive deficits are caused by interference with the descending motor pathways and the ascending proprioceptive fibers in the brainstem and may precede or accompany cranial nerve dysfunction. The fever occurs early in the disease course and often disappears after 3 to 5 days. Head pressing and propulsive walking or compulsive circling are caused by lesions of the basal ganglia.

1045 1046

Cranial nerves (CNs) V through XII usually are dysfunctional in listeric animals. Patients with loss of the trigeminal nerve (CN V) show dropped jaw or asymmetric jaw closure and facial analgesia or anesthesia. Facial analgesia is best detected by stimulation of the nasal septum with a pencil or piece of straw. Animals with lesions of CN VI exhibit a medial strabismus on the ipsilateral side of the lesion. Animals with lesions of CN VII have ptosis, loss of menace response, absent palpebral reflex, drooped ear, loss of levator nasolabialis muscle function, and decreased lip tone (Fig. 35-18). Small ruminants with CN VII loss have a deviated philtrum. The paralysis of the orbicularis oculi muscle results in exposure keratitis and, in chronic cases, panophthalmitis.[1492] The loss of levator nasolabialis function is best detected by observation of the muscular

contraction on the dorsum of the nose during inspiration. Loss of lip and cheek muscle tone is best detected by observation of drooling of saliva from the ipsilateral side of the mouth and by palpation of the lips and nostrils.

Animals with CN VIII lesions display a nystagmus that changes as the position of the head is altered. Other signs include a head tilt toward the side of the lesion and a tendency to circle or fall to the lesion side. The nystagmus may be horizontal, vertical, or rotatory and usually is inconstant. Goats may lie on their backs with the head curved toward the trunk and tilted with the lesion side toward the ground. If the spinal reflexes can be tested, the affected animals show a mild to moderate hypertonia and hyperreflexia in the limbs opposite the side of the lesion. Lesions of the cerebellar peduncles (juxtarestiform body) may cause paradoxic vestibular signs in which the head tilt and circling are directed away from the side of the lesion and proprioceptive deficits are on the same side as the lesion.[1493] This should be suspected whenever the head tilt is directed toward the side opposite that of the other dysfunctional cranial nerves. Animals with acute loss of CNs IX, X, and XII develop stertorous breathing and dysphagia. Animals with dysfunctional CN XII have paresis or paralysis of the tongue. With unilateral lesions the tongue protrudes from the side of the mouth ipsilateral to the lesion. Progression of listeriosis is associated with decreased consciousness, coma, and convulsions.

Fig. 35-18 Clinical appearance of the neurologic form of listeriosis in a Charolais bull. Note the dropped right eye and ear and the drooling of saliva from the right side of the mouth. Courtesy Dr. W.D. Wilson.

Lambs may selectively develop spinal myelitis without brainstem disease. This condition results in flaccid paraparesis or hemiparesis without attendant signs of brainstem dysfunction.[1494] The clinical signs of myelitis include tetraparesis, tetraplegia, paraparesis, paraplegia, conscious proprioceptive deficits, and recumbency. The sensorium and appetite are normal in some affected animals and greatly depressed in others.[1495]

35.10.3 Clinical Pathology

The clinical signs of multifocal brainstem disease with fever in a ruminant are suggestive of listeriosis, *Haemophilus somnus* infection (cattle), or aberrant parasite migration. Examination of the cerebrospinal fluid (CSF) should be helpful for confirming a diagnosis of listeriosis, but the cell and protein concentrations of the specimens do not correlate with the severity of the clinical signs or the prognosis. The protein concentration in the CSF may be over 40 µg/dL, and the CSF white blood cell (WBC) counts may be more than 12 mononuclear cells/µL.[1487,1496,1497] Many cattle with advanced signs of listeriosis develop metabolic acidosis as a result of salivary bicarbonate loss.

35.10.4 Pathology

Pathologic confirmation of listeriosis is based on identification of multifocal microabscesses in the brainstem and isolation of *L. monocytogenes* from infected brain tissue. The agent is only rarely isolated from CSF and is best recovered from refrigerated nervous tissues. Enrichment of the *Listeria* organisms may be accomplished by refrigerating slices of brain at 4° C (39.1° F) for 3 months while culturing the tissues weekly. In contrast to septicemic listeriosis of monogastric animals, peripheral monocytosis is not observed in infected ruminants.

35.10.5 Pathophysiology

Listeria organisms produce a hemolysin, listeriolysin-O, a thiol-activated toxin (molecular weight, 58 kD) that is correlated with pathogenicity. The molecular role of the toxin in dissemination of the infection and in cell death is not known.

It is unclear whether infection of the brain by *L. monocytogenes* occurs hematogenously or by ascent from the cranial nerve rootlets.[1498] Morphologic studies of naturally occurring cases of encephalitic listeriosis have demonstrated the bacterium in the axons of the trigeminal nerve rootlets, indicating a possible centripetal migration.[1498,1499] Similar findings have been reported in animals infected experimentally.[1500] Younger animals may be susceptible because eruption of the permanent teeth may expose trigeminal nerve rootlets. A model for experimental induction of listeriosis by inoculation of the bacterium into the pulp cavity of sheep has been described.[1501] Infection of the CNS without bacteremia has been detected, indicating that centripetal migration of the bacterium is possible.[1502] Some investigators consider axonal migration as an unlikely mode of pathogenesis because of a lack of nutritional dependency of *L. monocytogenes* for nervous tissue and the ready ability to produce multifocal brain microabscesses by intravenous (IV) inoculation of the bacteria into susceptible hosts.[1498,1503]

35.10.6 Epidemiology

L. monocytogenes has 16 major serologic types based on comparison of somatic and flagellar antigens. Most clinical infections are caused by serovars 1/2a, 1/2b, 4a, and 4b. *Listeria ivanovii,* usually associated with abortions in sheep, also has been classified as *L. monocytogenes* serovar 5. The serovar 1/2 (a and b subtypes) is most prevalent in livestock. The 1/2b subtype appears to be exclusively related to encephalitic infections, whereas other subtypes, including 1/2a, can be associated with any of the clinical forms of listeriosis.[1504] The pathogenicity of serovar 1/2a is hemolysin dependent. Serogroup 1/2 (a or b type) is most often isolated from feedstuffs. Serovar 4b is responsible for most infections in humans.[1505]

The case-attack rate in ruminants may reach 9% but rarely is greater than 2%.[1506] Listeriosis occurs sporadically in weaned lambs confined to a drylot and appears in only a small proportion of the lambs at risk. The encephalitis usually occurs from 4 to 32 days after weaning and at 6 to 12 weeks of age. Between 0.7% and 1.6% of all lambs at risk may develop the infection.[1507] In untreated cases the fatality rate is almost 100%.[1491] The survival rate in treated animals is considerably higher than in untreated patients. The disease in sheep and goats tends to be more acute and results in a higher case-fatality rate than in cattle. Occasional outbreaks of listeriosis may occur in sheep without access to silage.[1491,1508] In these cases the source may be the feces of carrier animals or rotting vegetation on the pastures or feed bunks. During an outbreak of listeriosis, the bacterium can be isolated from the feces of a large percentage of normal animals.[1509] It is unclear whether this high rate of asymptomatic infections represents a true carrier state or is simply the result of a high environmental contamination by nonpathogenic isolates.[1509] The agent infects the udder but rarely causes clinical mastitis. In sheep, excretion of the bacterium in the milk is greatest during the immediate postlambing period.[1510,1511]

Listeria monocytogenes can survive for long periods in the environment and in asymptomatic carriers. The bacterium can multiply at low environmental temperatures and is resistant to environmental influences. *L. monocytogenes* is shed in the feces of asymptomatic carriers, especially at the end of pregnancy and at lambing. Once in the environment, the bacterium can survive for 2 years in dry soil. It is resistant to freezing and thawing in the soil but does not survive for more than 1 to 2 weeks in properly preserved silage. The bacterium proliferates in rotting vegetation in which aerobic conditions exist and the pH is above 5.4.[1512–1514] Common sources of contaminated forage include spoiled silage at the ends of trench silos, decaying forage at the bottom of feed bunks, or rotting hay at the periphery of hay stacks.[1512,1515] The incidence of listeriosis may be increasing because of the greater use of trench silos and bulk handling methods that result in a greater amount of spoilage than in conventional upright silos. Although *L. monocytogenes* can be isolated from silage with a pH below 4, fewer bacteria are found in well-preserved forage.[1516]

A selective enrichment medium has been developed for identifying and enumerating the *Listeria* organisms in silage. This medium permits semiquantitative enumeration of *Listeria* bacteria in 10 g of silage. Hemolysin production is measured by overlaying the colonies with bovine blood agar and reincubating the plates. Using this method, outbreaks of listeriosis have been correlated with silage containing 1 million *Listeria* organisms and more than 1 million enterobacteria per gram of silage. The pH of such silage characteristically is above 7.8.[1517]

There is a significant public health concern about *Listeria* contamination of milk products. The 4b serotype of *L. monocytogenes* is most often responsible for infections in humans.[1518] Outbreaks have been traced to

ingestion of pasteurized milk, cole slaw, and soft, ripened cheese. The occurrence in cheese has led to concerns that the bacterium may survive the pasteurization process[1519]; however, heat resistance by *Listeria* organisms does not appear to be a significant factor in milk-related human exposures. One study indicated that intracellular *Listeria* bacteria survived after exposure to temperatures as high as 73.9° C (165° F) for 16.4 seconds. Complete killing of the *Listeria* organisms required temperatures as high 76.4° C (169.5° F) for 15.4 seconds. These temperatures exceeded the minimum temperatures required by the U.S. Food and Drug Administration (71.7° C [161° F] for 15 seconds).[1520] The public health implications of these findings are unclear.

35.10.7 Pathologic Lesions

The lesions of listeric meningoencephalitis are most common in the pons and the trapezoid bodies, but they can be located anywhere in the brainstem. Neurologic structures most often affected include the reticular formation and CNs V and VII to X. Macroscopic lesions are limited to mild meningeal congestion and clouding of the CSF. Microscopic lesions include perivascular cuffing with mononuclear cells, multifocal asymmetric brainstem microabscesses, and mononuclear cell meningoencephalitis.[1521] The microabscesses are composed predominantly of neutrophils. Other microscopic changes include degeneration of the neuropil and neuronophagia. To enhance the speed and accuracy of pathologic diagnosis, a peroxidase-antiperoxidase method has been developed for use with formalin-fixed nervous tissue. The test detects degraded bacterial proteins, as well as intact bacteria in the suspect tissue. Bacterial antigen is exclusively located in areas of malacia or in the microabscesses.[1522]

35.10.8 Treatment

The recovery rate is best if treatment is administered early in the disease course. Animals that are recumbent, comatose, or convulsive rarely survive despite intensive antibiotic and supportive therapy. In most cases, treatment must be administered for a prolonged period because recovery may take as long as 1 month. *L. monocytogenes* is susceptible to most of the common antimicrobial drugs. Recommended treatment is either oxytetracycline, 10 mg/kg intravenously (IV) twice daily, or penicillin G.[1492] Specific recommendations for penicillin therapy include an initial dosage of 40,000 IU/kg (IV potassium penicillin G) three or four times daily for 7 days and then 22,000 IU/kg (procaine penicillin) intramuscularly (IM) once daily for 14 to 21 additional days.[1492]

The plasma concentrations of bicarbonate and potassium should be measured and specific corrective fluid therapy administered. Maintenance fluids also may be administered by gavage. Good footing and nursing care are helpful in the short term but may not influence the overall recovery rate.[1523]

35.10.9 Prevention

Serologic responses to flagellin and listeriolysin-O develop after oral administration of virulent *L. monocytogenes* and correlate with protection against listerial bacteremia.[1502] Cell-mediated immune responses also are important in protection against virulent challenge. Vaccines of attenuated or killed bacteria have been used successfully to protect sheep and goats. Although these vaccines reduce the incidence of listeriosis in vaccinated flocks, they are not commercially available in the United States.

Although the case-attack rate of listeriosis is low, occasional epizootics may occur in cattle, sheep, or goat herds, invariably associated with high rates of environmental contamination. In such cases the hay and silage should be examined culturally for *L. monocytogenes*. Rotten vegetation should be discarded, and cattle should be fenced from contaminated areas.

1047

1048

35.11 THROMBOEMBOLIC MENINGOENCEPHALITIS (*HISTOPHILUS SOMNI [HAEMOPHILUS SOMNUS]* INFECTION; SLEEPER CALVES)

35.11.1 Definition and Etiology

Thromboembolic meningoencephalitis (TEME) is a fulminant neurologic disease of cattle that arises from septicemia caused by the pleomorphic, nonencapsulated, gram-negative bacterium *Histophilus somni* (formerly *Haemophilus somnus*).[1524] The disease was first reported in Colorado in 1956,[1525] but characterization of the etiologic agent, *H. somni,* was not completed until 1960.[1526] The disease is economically significant for livestock owners. One study in feedlots of western Canada indicated that the average economic loss from TEME resulted in 15 sick animals and five deaths annually, amounting to $3190 in lost revenue.[1527] In addition to TEME, disease syndromes that have been associated with *H. somni* infection include pneumonia, infertility, metritis, vulvitis, orchitis, conjunctivitis, otitis, and mastitis.[1528–1530] The bacterium has been isolated from unthrifty calves, but its causative relationship to that syndrome is unclear.

Cross-agglutination, complement fixation tests and countercurrent immunoelectrophoresis have shown the existence of common surface antigens among isolates of *H. somni*.[1531] Nevertheless, differences in the susceptibility of heterologous isolates of *H. somni* to antibody and complement have been identified.[1532] Isolates from septicemic animals are serum resistant, whereas those from preputial or vaginal mucosa of healthy animals tend to be serum susceptible.

35.11.2 Clinical Signs

Only the neurologic syndrome (TEME) is discussed here. Descriptions of other clinical syndromes of *H. somni* infection are discussed in Chapters 31, 39 and 43. The neurologic signs of TEME occur peracutely and may be preceded for 1 to 2 weeks by a dry, harsh cough and dyspnea.[1533] Death may occur within 36 hours after the onset of neurologic signs. The initial signs of TEME are fever (40° C to 41.6° C; 104° F to 107° F), anorexia, depression, and ataxia.[1534–1536] In addition to depression, affected animals show a number of conscious proprioceptive deficits, including knuckling, circumduction, crossing over, and interference.[1536] Affected animals may fall while attempting to walk. Signs specifically associated with lesions of the cerebellum and caudal brainstem include head tilt, nystagmus, strabismus, blindness, muscular tremors, opisthotonos, coma, and convulsions.[1537] Auscultatory abnormalities in the chest include harsh bronchovesicular sounds and pleural friction rubs. Localization of the bacterium in the joints or lungs may result in lameness, joint swelling, and fluctuant swellings over the joint surface. Other signs observed in some animals include retinal hemorrhages, hyphema, and hypopyon.[1535,1538]

After recovery from the pneumonia, some affected animals may develop pleuritis, necrotic laryngitis, and weight loss.[1539] Some symptomatic animals and as many as 10% of inapparently infected cattle may develop suppurative arthritis of the hock and the stifle joints.

35.11.3 Clinical Pathology

Examination of CSF may be helpful in substantiating a clinical diagnosis of TEME. Specific CSF changes characteristic of hemorrhage include high erythrocyte counts, xanthochromia, and increased concentrations of protein (>100 mg/dL) and neutrophils (>500 WBCs/μL). In untreated cases of TEME, the bacterium may be isolated from pleural fluid, lung sections, aspirated tracheal exudate, urine, blood, and preputial washings. The bacterium can be isolated from 25% to 34% of all fatally infected cattle.[1537] *Histophilus* organisms die rapidly on swabs or transport media, so specimens should be inoculated directly onto a growth medium as soon as they are collected from the patient.[1530] The inoculated medium should be incubated in an atmosphere containing 5% carbon dioxide. Isolation of *H. somnus* from joint fluid and CSF usually is unsuccessful.[1540] The kidneys and brain should be collected at postmortem examination because these tissues contain the highest concentrations of *H. somni*.[1540]

Initial changes in the peripheral WBC count include neutropenia, left shift, and toxic changes in the neutrophils. A test for serum agglutinins has been developed. Cattle that develop acute TEME invariably have antibody titers greater than 1:400 and show a fourfold increase by 2 to 4 days after infection.[1541] Serum agglutination titers greater than 1:1024 are seen in convalescent cattle; lower titers may be seen with inapparent infection or vaccination.[1542]

35.11.4 Pathophysiology

Infection of cattle by *H. somni* probably occurs through the respiratory tract. Bacterial proliferation in the lungs and other soft tissues by serum-resistant isolates results in bacteremia. Circulating *Histophilus* organisms are phagocytosed by neutrophils but are not killed. Blood-borne bacteria also adhere to and may be phagocytosed by the cells of the vascular endothelium. The infected endothelial cells then degenerate and desquamate, exposing the subendothelial collagen and initiating the blood-clotting cascade and thrombosis.[1543] Death of neutrophils in the tissues is thought to enhance the tissue damage.[1544,1545] The sites of the body most affected by the thrombosis are the brainstem, spinal cord, synovial membranes, pleura, and lungs. Although the name “thromboembolic meningoencephalitis” implies the presence of disseminated coagulopathy, only local thrombus formation likely occurs at the specific vascular lesion. Immunologic mechanisms may play a role in the vascular lesion. Thrombosis occurs most often in animals with high levels of specific agglutinating antibodies and is not seen in colostrum-deprived calves with *H. somni* septicemia, indicating the importance of antigen-antibody complexes for the development of vasculitis.[1546]

Cattle probably develop immunity to *H. somni* infection; however, the presence of serum antibodies does not always confer substantial protection against challenge exposure by virulent bacteria.

35.11.5 Epidemiology

Most cattle develop *Histophilus* infection by inhalation of contaminated respiratory secretions from carrier animals. Although TEME occurs most frequently in feedlot cattle,[1536] outbreaks in the western United States and Canada have been reported in both pasture and dry-lot environments.[1534,1547] The disease occasionally may occur in adult cattle.[1527] Outbreaks of the neurologic form of TEME tend to occur in the winter months, after shipment or overcrowding, or after additions to the herd in the previous 7 months. Outbreaks usually are

preceded by a poorly defined respiratory infection.[1527] In feedlot outbreaks the disease frequently is restricted to herdmates in a single pen or pasture.

Transmission of *H. somni* from asymptomatic carriers to uninfected calves may be enhanced by concomitant infection with infectious bovine rhinotracheitis virus.[1535] The anatomic site of bacterial infection in the carrier animals is unknown. *Histophilus* organisms can be readily isolated from the vaginal and urethral epithelium and from urine, the preputial cavity, and accessory sex glands, but the relationship between these isolates and those found in TEME is unknown.[1548] Although random bacteriologic surveys of cattle indicated that 71% of bulls may have *H. somni* in the preputial orifice, the concentration in the nasal secretions and upper respiratory tract epithelium in cattle with TEME is low.[1548] Consequently, some investigators have suggested that the urogenital tract may constitute the primary colonization site in chronically infected cattle.[1548] Differences exist in serum susceptibility of isolates from the CNS and from the urogenital tract.[1532]

1048 1049

The seroprevalence rate may be as high as 100% in some endemic herds and may range from 25% to 56% in herds in which the CNS disease is uncommon. In comparison, the case-attack rate of TEME ranges from 2% to 7.4%.[1549] Repeated annual outbreaks can occur in some herds. Estimates of the proportion of carrier animals in feedlots range from 3.2% to 8.8%.

35.11.6 Necropsy Findings

Cattle with the neurologic lesions do not tend to develop fibrinous pneumonia. Macroscopic pathologic lesions of the CNS include disseminated multifocal hemorrhages and 0.1-cm to 0.3-cm infarctions in the spinal cord, brainstem, and cerebral cortex. Bacterial colonies frequently are observed in thrombosed blood vessels and the surrounding infarcted tissues. Ocular lesions are characterized by conjunctivitis, multifocal retinal hemorrhages, and areas of retinal edema. The CSF is cloudy and xanthochromic. A focal fibrinous meningitis is seen, and suppurative otitis may be seen in some cases.

The earliest microscopic lesion of TEME is a vasculitis that progresses to septic infarction and abscessation. The lesions usually are found in the CNS but in severe cases may be disseminated throughout the body.

Nonneurologic lesions of *H. somni* infection include suppurative arthritis, synovitis, suppurative pleuritis, and bronchopneumonia. Changes associated with the bronchopneumonia include infarction, cranioventral pulmonary consolidation, and hemorrhagic interstitial pneumonia. Simultaneous pulmonary infections with *H. somni* and *Pasteurella multocida* result in particularly severe pathologic changes.[1550] These lesions include ecchymotic to petechial hemorrhages over the serous surfaces, purulent exudate in the joints, and ulceration of the laryngeal and tracheal mucosa with pseudodiphtheritic membrane formation.[1551]

35.11.7 Treatment and Prognosis

During an outbreak, cattle must be examined frequently and should be treated when the neurologic signs first appear. *H. somni* is susceptible to many antibiotics and antimicrobial drugs. Drugs that have been reported to be effective for the treatment of TEME include tetracyclines, penicillin, aminoglycosides, and ampicillin. Parenteral oxytetracycline is regarded as the most cost-effective treatment for infected commercial cattle; dosage is 10 mg/kg of a conventional formulation given IV twice daily for 3 days or 20 mg/kg of a long-acting formulation given IM every other day for three treatments. After oxytetracycline therapy, daily treatment with procaine penicillin (10,000 to 20,000 IU/kg IM) should be continued until complete recovery is observed. Some

advocate the addition of chlortetracycline (2.2 mg/kg) to the feed for 10 successive days.[1552] This method of mass therapy for a TEME epizootic is considered more efficacious than vaccination when the mortality is less than 2%.[1552]

35.11.8 Prevention and Control

Antibody responses protective against respiratory challenge have been generated by vaccinating cattle with anionic, heat-stable proteins derived from the bacterial cell wall.[1553] In comparison, cattle vaccinated with cationic cell wall proteins developed precipitating antibodies but were not protected against challenge exposure.[1553] Bactericidal antibodies may constitute important mechanisms for host resistance against *H. somni*.[1545,1550] Vaccination of cattle with commercial products affords substantial protection from experimentally induced *H. somni* septicemia and neurologic disease[1533,1554] for as long as 95 days after vaccination.[1533] (See Chapter 48 for more information about vaccines.)

Mass prophylactic treatment of affected cattle with a parenterally administered, long-acting oxytetracycline formulation may be efficacious for preventing TEME in cattle that have been stressed and exposed to carrier animals.[1555] Oxytetracycline feed additives also may be useful for preventing *H. somnus* infection.[1551] One field study indicated that administration of modified live virus vaccines for infectious bovine rhinotracheitis and bovine viral diarrhea on arrival at a feedlot significantly increased the incidence of TEME.[1550] Such data indicate that modified live virus vaccines should be administered cautiously to cattle exposed to *H. somni*.

35.12 BACTERIAL OTITIS MEDIA-INTERNA OF RUMINANTS

Otitis media-interna is a common disease of cattle and sheep. The condition usually occurs as a sequel to severe respiratory infections caused by *Pasteurella haemolytica, Pasteurella multocida, Corynebacterium pseudotuberculosis, Pseudomonas aeruginosa, Histophilus somni,* or *Mycoplasma* species.[1556–1561] Bacterial ear infections are common in feedlot-reared lambs. The incidence may range from 2.9% to 12% of all animals raised under those conditions, and in these animals the condition usually is subclinical.[1556–1565]

Suppurative bacterial otitis is characterized by thickened mucosae of the vestibular membranes and accumulation of thick fluid in the labyrinths. The infection enters the ear through the eustachian tube. The tympanum may be intact in sheep.[1559] In calves, however, it usually is ruptured, and a clear, yellow, proteinaceous fluid is discharged through the external ear canal; the fluid then accumulates at the base of the ear.[1558,1566] In chronic cases of bacterial otitis, invasion of the local bone of the skull may result in bone remodeling and hyperostosis.[1561]

Vestibular disease results from infections that extend into the inner ear. Patients with vestibular signs display heat tilt (toward the side of the lesion), continuous horizontal nystagmus (fast phase away from the side of the lesion), and a tendency to stumble or fall toward the side the lesion. Head shaking with development of an aural hematoma may precede the clinical vestibular signs. Animals may become recumbent[1561] and lie with the lesion side toward the ground; if turned, they return to the same position. If the lesion involves the cerebellar peduncles, the animal develops paradoxic signs. In this case the head tilt is away from the lesion side, the fast phase of the nystagmus is toward the lesion side, and the patient circles away from the lesion side. Many animals with otitis media also develop facial nerve dysfunction, which results in ptosis, drooped ear, and flaccid lips and nostrils. In small ruminants, facial nerve paralysis results in deviation of the philtrum toward the normal side. Deviation of the philtrum does not occur in cattle because of the large amount of connective tissue surrounding the planum

nasale. Sheep with *Pseudomonas* otitis may develop necrotizing dermatitis of the ear canal. Some affected sheep also develop signs of cortical or brainstem disease, including unilateral blindness and contralateral mydriasis. These signs occur when the infection extends from the middle ear into the meninges. 1049 1050

Although the clinical signs of peripheral vestibular disease are characteristic, it is important to differentiate this condition from that of central vestibular disturbance. Animals with peripheral vestibular disease usually are appetent, alert, and aware of their surroundings and do not have a significant deficit of postural placement. The nystagmus of these animals is constantly horizontal. In comparison, animals with central vestibular disturbances are systemically depressed, have a nystagmus that varies in direction, and show marked conscious proprioceptive abnormalities.

Treatment of bacterial otitis with oxytetracycline (6 mg/kg IM or IV daily or 20 mg/kg of long-acting formulation IM every other day) or procaine penicillin (40,000 IU/kg IM daily) may be effective. Drug therapy should be continued for several weeks to prevent relapses. Treatment is very effective in obtaining a complete cure in animals with acute otitis but is less so in the chronic form. Otic instillation of aminoglycoside antibiotics is contraindicated. Lincomycin (6.5 mg/kg) and spectinomycin (10 mg/kg) have been used successfully when oxytetracycline or trimethoprim-sulfonamide therapy has failed.[1558] Other drugs that have been beneficial for the treatment of otitis include ampicillin, gentamicin, and enrofloxacin. Animals that do not respond should be examined for an abscess or squamous cell carcinoma invading the calvarium or osteomyelitis of the petrous temporal bone.

35.13 EAR MITE INFESTATIONS OF RUMINANTS

The ear mite of cattle is *Raillietia auris,* and that of small ruminants is *Psoroptes cuniculi*. Cattle that become infected with the ear mite develop a hearing impairment. Severe infestations perforate the tympanum and result in vestibular disease, facial paralysis, and ataxia.[1567–1570] Infected sheep and goats shake their heads vigorously and develop aural hematomas.[1571] Infestation of cattle can be recognized by observation of ulceration and purulent debris in the auditory canal next to the tympanum. In cattle, mites may be entrapped between the plug and the tympanum and may not be visible during an otoscopic examination. All infested cattle have pus and ulceration of the ear canal.[1572] A foul-smelling discharge on the side of the face under the ear canal may be seen in some affected animals. Chronically affected cattle develop a hearing loss for high-frequency sounds.

The psoroptic ear mite of small ruminants does not spread over the remainder of the body. The accumulation of purulent debris and swelling of auricular tissues block the transmission of sound to the tympanum.

Ear mite infestations in cattle are common and in some herds may affect most of the adults. One U.S. study reported a prevalence rate of 66% (29 of 44 cattle).[1567] The biologic importance of the infestation may be related to changes in the herding or mothering behavior of range cattle. The economic significance of the infestation is unknown. The parasite can complete a full life cycle by 8 days.

Ear mites have been successfully treated in goats using ear drops containing rotenone[*] once daily for 5 to 10 days. Good clinical responses can be obtained in cattle with the same treatment. Fenthion (Spotton,[†] 0.2 mL) drops also have been used successfully. In cases of parasitic otitis in which the discharge has been inspissated, lateral resection of the ear canal should be considered to establish adequate ventral drainage.[1573] The addition of nicotine to final concentrations of 2 ppm in dip tanks containing 0.25% toxaphene has been 95% effective in some outbreaks.[1574] Plunge-dipping in diazonon, propetamphos, or flumethrin, pour-on preparations of synthetic pyrethroids, and oral dosing with ivermectin all are ineffective.[1574] A single subcutaneous (SC) injection of

ivermectin at 0.2 mg/kg has been shown to be an effective treatment for *P. cuniculi* otitis in both sheep and goats.[1574,1575]

The life cycle of the mite involves two free-living stages, the proto and the deuto nymphs. These forms molt in the vegetation and reinfest cattle as they graze or bed during the evening.[1576] Therefore, tilling the soil of the infested pastures or re-treating cattle every 14 to 21 days with insecticide should be considered as part of an eradication scheme.

A recent report of neurologic dysfunction in a cow with *Raillietia* infestation highlights the importance of thorough evaluation before diagnosis.[1577] This cow also had listeriosis, the more likely cause of the neurologic signs.

35.14 SPACE-OCCUPYING LESIONS OF CRANIAL NERVES IN CALVES

LISLE W. GEORGE

An epizootic disease of Groningse Blaarkop calves characterized by facial paralysis and vestibulocochlear disease has been identified.[1578] The calves showed drooped ear, loss of vision with normal pupillary reflexes, head tilt, dorsolateral strabismus, circling, and depression. One calf had a mild fever, dysphagia, and mandibular paralysis. The CSF contained a high WBC count and an increased total protein level. The disease was caused by multifocal space-occupying lesions that surrounded the cranial nerves at the entrance of the calvarium. The microscopic lesions consisted of granulomatous inflammation of the nerves at the internal acoustic meatus and the facial canal. The inflammatory cells in the lesions consisted of histiocytes, lymphocytes, multinucleated giant cells, and plasma cells. The specific etiologic agent was not identified. The granulomas did not contain acid-fast bacilli, fungal elements, or *Listeria monocytogenes*. The microscopic appearance of the lesions and their location in the nervous system were similar to cauda equina neuritis in horses. The disease in the calves was nonprogressive, and some of the calves recovered, which differentiates the calf disease from the progressively fatal cauda equina neuritis in horses.

35.15 PERIPHERAL VESTIBULAR DISEASE OF HORSES

35.15.1 Definition and Etiology

Vestibular disease of horses is an acute, asymmetric condition with one of several causes: extension of pyogenic bacterial infections from the guttural pouch, polyneuritis equi, viral labyrinthitis, and traumatic skull fractures.[1579–1581] Idiopathic labyrinthitis probably represents an acute viral inflammation of the vestibular system that is severe,[1580] but spontaneous recovery is common. Lightning strike also has been suspected as the cause of vestibular signs in horses.[1582]

Vestibular disease may also be caused by pyogenic inflammation of the petrous temporal bone or membranous labyrinths. Staphylococci, streptococci, and *Aspergillus* species have been isolated from cases of suppurative otitis in horses.[1579,1583] Two forms of suppurative otitis media-interna have been identified.[1579,1583] In the least severe form, the pyogenic inflammation localizes in the petrous temporal bone but does not spread into the

calvarium or rupture the tympanum. This infection results in vestibular signs. This mild form of otitis media-interna also causes dysfunction of CNs VII and VIII.

35.15.2 Clinical Signs

The clinical course of peripheral vestibular disease may be chronic with acute exacerbations. Recovery is common with appropriate therapy. The more severe form occurs when the pyogenic inflammation extends outward into the temporohyoid joint and stylohyoid bone.[1583] The inflammatory process fuses the tympanohyoid joint, which fractures during strong contractions of the muscles of the pharynx and neck. The fracture line extends into the calvarium, resulting in hematoma formation in the CNS. Pyogenic agents from the original septic site may then gain access to the CNS and cause meningitis. The clinical signs are peracute, and mortality is high. Extension of the fracture lines along the cranial vault and osteomyelitis result in dysfunction of CNs VII and VIII and the cerebrum. Affected horses show a rapid deterioration in mental status immediately after the initial onset of clinical signs. Involvement of the temporohyoid bone can be recognized on radiographic examination of the head and pharynx. The radiographic changes include thickening and pathologic fracture of the stylohyoid bone and tympanosclerosis.

Early clinical signs may appear to be unrelated to the CNS. The horse may appear to be uncomfortable and may shake the head or rub the affected ear for 2 to 3 weeks before the onset of vestibular signs. Otorrhea is not usually observed. The neurologic signs appear suddenly. Horses with mild disease develop ataxia, head tilt, facial paralysis, and nystagmus. The nystagmus is not changed by movement of the head (rapid phase away from the side of the lesion). There also is a ventrolateral strabismus on the side of the lesion. The affected animals circle or more often lean against the stall walls for support. Frequently, a mild conscious proprioceptive deficit is worse on the affected side. Horses with severe calvarium fractures fall and become recumbent. They lie with the side of the lesion facing the floor. Because of the proximity of the facial nerve to the vestibular apparatus in the petrous temporal bone, most affected horses also show signs of facial palsy, including drooped ear and lips, drooling of saliva, ptosis, exposure keratitis, and deviation of the philtrum toward the opposite side of the lesion (Fig. 35-19). If extensive bleeding into the calvarium has occurred, the animal becomes blind in the eye contralateral to the side of the hematoma. Pressure in the cerebral cortex may result in mydriatic pupils on the ipsilateral side. Lesions located central to the geniculate ganglion denervate the lacrimal glands and result in keratitis sicca.

Horses with lesions of the peripheral vestibular system remain appetent and alert. In comparison, animals with vestibular disease accompanied by petrous temporal bone fractures and meningitis tend to be depressed, febrile, and inappetent. Animals that develop septic meningitis secondary to a temporal bone fracture show rapid deterioration of mental status, rigidity, or flailing of the limbs with mild stimulation, stiffness of the neck, hyperesthesia, fever, otorrhea, and dysphagia.[1584]

35.15.3 Diagnosis and Treatment

Ancillary diagnostic measures for vestibular disease in horses include skull radiographs and endoscopic examination of the guttural pouch to exclude the possibility of tympanosclerosis, fractured hyoid bone, or fungal otitis. Otic examination in the horse in difficult because of the external ear anatomy in this species and the resistance of horses to this type of examination. Chemical restraint and the use of video otoscopy can facilitate both otoscopic examination and the sampling of material from the external ear for microscopic examination and culture.[1585] The rate of tear secretion may be tested with a Schirmer tear test strip. The normal rate of tear secretion is approximately 21 mm/min, whereas deficient tear production is less than 17 mm/min.

Brainstem auditory-evoked response testing may help to establish the localization of vestibular signs as peripheral in origin rather than central.[1586]

Fig. 35-19 Head tilt and right-sided facial paresis in a horse with peripheral vestibular disease. Courtesy Dr. W.D. Wilson.

Antibiotic treatment of peripheral vestibular disease should include high doses of penicillin (20,000 to 40,000 IU/kg IV four times daily) or, as an alternative, a third-generation cephalosporin or trimethoprim-sulfonamide combination. The alternative drugs should be considered when infection by penicillin-resistant bacteria is suspected. One study reported clinical improvement in patients treated with chloramphenicol (10 mg/kg orally four times daily).[1583]

Patients with early cases of vestibular disease may benefit from treatment with nonsteroidal antiinflammatory drugs (NSAIDs). Administration of corticosteroids in the acute stages of the disease may ameliorate the clinical signs, but the beneficial antiinflammatory effects of these drugs should be weighed against the potential for nonspecific immune suppression and ultimate extension of pyogenic foci into the CNS along cracks in the calvarium.

Affected horses should be kept in a quiet, heavily bedded stall with good footing. Exposure keratitis may be treated by performing a tarsorrhaphy or by repeatedly administering petrolatum ophthalmic-lubricating ointments. Horses with keratoconjunctivitis sicca may be treated with 0.25% pilocarpine eyedrops four times daily.[1587]

Horses that recover after long-term antibiotic therapy should be used cautiously because subtle neurologic deficits that interfere with coordinated motor activities could precipitate catastrophic accidents. Relapses may occur in some seemingly recovered patients.

35.16 EXOPHTHALMOS AND STRABISMUS OF CATTLE

LISLE W. GEORGE

A heritable exophthalmos and strabismus of Jersey, Holstein, Brown Swiss, and shorthorn cattle has been described.[1588–1591] The defect is characterized by protrusion of the eyeballs and anteromedial rotation of the eye around the axis (cross-eyed). The defect does not become evident until the animals are over 6 months of age. Affected animals have defective vision and show difficulty walking in unfamiliar environments. Both genders are affected. The condition in Holsteins is thought to be related to a decreased number of nerve cells in the abducens motor nucleus.

35.17 NIGROPALLIDAL ENCEPHALOMALACIA (YELLOW STAR THISTLE POISONING; RUSSIAN KNAPWEED POISONING)

35.17.1 Definition and Etiology

Nigropallidal encephalomalacia is a disease of adult horses characterized by facial dystonia, variable ataxia, mild depression, and food retention in the mouth. The disease is caused by ingestion of large quantities of the plants *Centaurea solstitialis* (yellow star thistle) or *Centaurea repens* (Russian knapweed).[1592–1595]

35.17.2 Clinical Signs

The signs appear suddenly but always after long-term ingestion of large quantities of the plants. Characteristic signs of nigropallidal encephalomalacia common to all cases include weight loss, mild to moderate depression,

conscious proprioceptive deficits, yawning, lowered head, protruding tongue, tremor of the tongue and lips, and facial hypertonicity when feed is offered. The facial hypertonicity causes a retraction of the lips, resulting in a fixed grimace with the mouth and lips held half-open (Fig. 35-20). The patient may display constant chewing movements, and prehension, mastication, and deglutition of food are uncoordinated and inefficient. Affected horses can grasp food in their incisors but are unable to chew adequately and propel the food to the back of the mouth. Food retained in the mouth and cheek pouches may protrude from the commissures of the lips. Affected animals may attempt to drink by immersing their muzzles deeply into the bucket to force the water into the back of the pharynx. Once the food or water is in the posterior part of the pharynx, the animal is able to swallow. Affected animals die of starvation or dehydration. Horses that appear to be depressed usually can be aroused by mild stimulation. Motor and sensory deficits include hypertonicity, ataxia, conscious proprioceptive deficits, and occasionally hypermetria. There also may be a transient tendency to walk propulsively or to circle. Occasionally the animals are hyperexcitable. After several days the signs stabilize, and the disease does not progress. Affected animals usually do not recover.

Fig. 35-20 Characterisitc facial expression of a horse with nigropallidal encephalomalacia. When the animal is offered feed, the marked dystonia of the facial muscles, caused by loss of upper motor neuron inhibition, becomes obvious. Courtesy Dr. G.P. Carlson.

35.17.3 Diagnosis

The CSF of affected horses may show increases in WBC count (75/dL).[1594] There are no characteristic changes in the complete blood count (CBC) or the serum chemistries. Magnetic resonance imaging (MRI) was used to make an antemortem diagnosis in one horse with nigropallidal encephalomalacia.[1596]

35.17.4 Pathophysiology

The toxic principle in the plants has been isolated and chemically characterized. The toxic molecule is called *repin,* a sesquiterpene lactone with high affinity for neural tissue.[1597–1600] Long-term feeding of alcoholic extracts containing repin to monkeys has resulted in collapse, convulsions, and death.[1601] Studies in rats suggest that repin exerts its neurotoxic effects by inhibiting dopamine release.[1600] Additional neurotoxic compounds, including aspartic and glutamic acids, also have been isolated from *Centaurea* plants.[1602]

35.17.5 Necropsy Findings

At necropsy, sharply demarcated areas of yellowish malacia are visible grossly in the substantia nigra and globus pallidus (extrapyramidal system). Lesions are bilaterally symmetric in more than 50% of cases but are asymmetric in a substantial proportion of affected animals. Lesions in other brainstem nuclei are found in a small number of animals.[1593,1603] Microscopic lesions include neuronal necrosis, vacuolation with gliosis, liquefactive necrosis, and cavitation in well-developed lesions.[1597]

35.17.6 Epidemiology

Nigropallidal encephalomalacia has been reported in horses of the United States, Australia, and South America. Yellow star thistle is a common plant in unirrigated pastures in the arid regions of the western United States. The plant is resistant to the effects of saline or alkaline soil conditions and has a minimum moisture requirement. Russian knapweed belongs to the sunflower family and grows predominantly on flood plains, where it can extract deep subterranean moisture. In the United States the plants tend to remain green during the dry months, so most poisonings occur during the summer or late autumn. Most horses are reluctant to eat *Centaurea* plants unless other vegetation is unavailable, but some develop a craving and selectively seek it out. Horses that develop nigropallidal encephalomalacia usually are being fed a poor-quality, high-roughage diet. Affected horses range from 4 months to 10 years of age (median, 2 years).[1597] The case-attack rates of yellow star thistle poisoning range from 3% to 31% of horses on infested pastures.[1597] Feeding studies have reported 1052
that as much as 59% to 200% of the body weight of yellow star thistle and 59% to 63% of Russian knapweed 1053
must be eaten over 3 to 11 weeks to cause clinical disease.[1593,1597] Continuous protracted exposure to the weeds seems to be important for expression of clinical disease. The dried plants retain their toxicity.

35.17.7 Treatment and Prevention

There is no known treatment for the poisoning. Prevention is best aimed at correcting the nutritional problem by daily supplementation with 10 to 15 lb of alfalfa hay and by not pasturing horses in areas where the thistle grows.

35.18 RUPTURED RECTUS CAPITIS VENTRALIS MUSCLES (TRAUMA TO CRANIAL NERVES IX, X, AND XI)

LISLE W. GEORGE

Traumatic avulsion of the rectus capitis ventralis muscle is seen exclusively in equids. The condition causes dysphagia. The muscle is ruptured when horses fall over backward and hyperextend the neck and head. Tearing of the tendinous insertion of the muscle damages CNs IX, X, and XI. The clinical signs include mild transitory epistaxis, laryngeal hemiplegia, dysphagia, and pharyngeal paralysis. Endoscopic abnormalities of the pharynx and larynx include mucoid discharge from the guttural pouch, pharyngeal and laryngeal paralysis, atonic proximal esophagus, and food particles in the trachea and bronchi.

Radiographic examination of the head and neck may be helpful for substantiating a clinical diagnosis. The radiologic lesions include irregular radiopaque lesions in the guttural pouch and fracture of sclerotic occipital and petrous temporal bones. These cases usually are associated with a preexisting mycotic lesion that results in bone weakness and pathologic fractures. The neurologic lesion usually is reversible, but affected horses may die of aspiration pneumonia before neurologic resolution.[1604]

35.19 HORNER'S SYNDROME

35.19.1 Definition and Etiology

Horner's syndrome results from interruption of ocular sympathetic pathways. Sympathetic fibers originate from neuronal cell bodies located in the mesencephalic tectum. Axons descend to the first to third thoracic (T1 to T3) segments of the spinal cord, where they enter the gray matter, synapse, and exit through the ventral spinal nerves. From there the nerves pass through the cervicothoracic and middle cervical ganglia (stellate ganglia) and ascend in the cranial vagosympathetic trunk.[1605] The nerves enter the cranial ganglion in the petrous temporal bone, where they synapse. The postganglionic fibers are distributed to the sweat glands of the head, ciliary muscles, periorbital smooth muscles, and periarteriolar musculature. Fibers of the vagosympathetic trunk or the cranial cervical ganglion can be injured as they pass through the neck or over the caudodorsal aspect of the guttural pouch.

Specific causes of Horner's syndrome include mycotic guttural pouch infections; traumatic lesions of the basisphenoid area; cervical trauma; abscesses, tumors, or space-occupying lesions in the anterior aspect of the thorax[1606,1607]; periorbital abscesses or tumors; parotid duct obstruction and inflammation[1608]; esophageal rupture; and complications associated with surgical ligation of the carotid artery. Intracranial lesions involving the central components of the sympathetic pathway in the ipsilateral brainstem are rare but have been reported as a consequence of metastatic neoplasia.[1609] Horner's syndrome also has occurred after IV injection of certain drugs, including xylazine, vitamin E or selenium, and phenylbutazone.[1610–1612] Horner's syndrome has also been seen in horses with polyneuritis equi (cauda equina neuritis) syndrome and equine protozoal myeloencephalitis of the cervical spinal cord.[1613,1614] Tumors that have resulted in Horner's syndrome include sclerosing respiratory epithelial carcinoma, squamous cell carcinoma, and melanoma.[1606,1607,1610,1615,1616]

35.19.2 Clinical Signs

The clinical signs of Horner's syndrome in horses vary but include miosis, enophthalmos, ptosis, regional hyperthermia, excessive sweating on the ipsilateral side of the face, congested mucous membranes, inspiratory stridor, and dermatitis caused by chronic sweating. Ptosis may be detected by palpation of decreased eyelid tone. The palpebral reflex and the menace response are normal. Facial sweating often disappears 6 to 14 days after sympathectomy. If concomitant damage to the cervical sympathetic nerves is present, sweating of the skin of the neck also may be seen. This is not observed in animals with lesions solely in the tectotegmentospinal pathway. Regional hyperthermia is caused by vasodilation, which results from deficient vasomotor tonus. Sweating is thought to be caused by vasodilation and increased cutaneous blood flow.[1617,1618] Increased sweating can be induced by β_2-agonists, including IV clenbuterol (200 µg) or isoprenaline (2 mg) or local application of 10% phenylephrine.[1619] Dysfunction of adjacent neurologic structures may result in simultaneous facial nerve paralysis and laryngeal hemiplegia. Bilateral Horner's syndrome has been reported in a horse with metastatic neoplasia affecting the sympathetic innervation of the head bilaterally.[1616] This horse had a mixed pattern of both preganglionic and postganglionic denervation caused by widespread metastases at multiple sites along the nerves.

In contrast to the disease in horses, cattle do not sweat on the planum nasale of the affected side. This can be explained by the mediation of normal sweat gland secretion by α-adrenergic receptors in the bovine.[1618] The other signs seen in cattle are similar to those in horses. The clinical signs of experimentally induced Horner's syndrome in sheep and goats are limited to a mild ptosis.[1618] Retrobulbar tumors may cause Horner's syndrome, but in these cases the eyeball proptosis results from the excessive retrobulbar pressure.[1615]

35.19.3 Diagnosis

The specific site of the denervation of the ocular sympathetic system usually can be located by pharmacologic testing.[1605] Hydroxyamphetamine (1% solution) instilled into the eye will result in release of norepinephrine from intact postganglionic sympathetic neurons, causing pupillary dilation, but no response when the postganglionic neurons are damaged. A positive response to this test indicates a preganglionic sympathetic lesion, and a lack of response indicates a postganglionic lesion. In animals with a postganglionic lesion, topical administration of 0.1 mL of 1:1000 epinephrine solution directly activates the iris musculature and produces mydriasis by 20 minutes, whereas the onset of dilation occurs at about 40 minutes in animals with preganglionic lesions. Similarly, 2.5% to 10% phenylephrine solution will produce pupillary dilation in an eye with a postganglionic sympathetic lesion, but not in a normal eye. The increased sensitivity to these direct-acting sympathomimetics in animals with postganglionic sympathetic lesions results from the phenomenon of "denervation supersensitivity," with numbers and sensitivity of norepinephrine receptors in the iris muscle increasing over days to weeks after postganglionic nerve injury. A positive response is therefore expected only after the nerve lesion has been present for at least several days. Parenteral administration of 1 mL of 1:1000 epinephrine solution causes affected horses to sweat profusely over the affected side of the face.[1610] However, this test does not differentiate between preganglionic and postganglionic lesions.

1053
1054

The guttural pouches of horses and the pharynx of all patients should be examined endoscopically to exclude the possibility of pharyngeal or laryngeal paralysis or guttural pouch disease. The jugular furrows should be palpated for swellings. Insertion of a nasogastric tube during palpation may be helpful for detecting subtle lesions on the left side of the neck. Radiographs of the cervical vertebrae should be obtained to exclude spinal

cord disease. The thorax should be examined using auscultation and percussion and, if indicated, radiographs taken. The gait and proprioceptive responses should be examined to evaluate the function of the spinal cord. The skin temperature may be measured using thermography[1607,1620]; on the affected side it is 1° C to 2.5° C (33.4° F to 37.5° F) higher than normal.

35.19.4 Treatment

The treatment for Horner's syndrome depends on the underlying cause of the denervation. Except for Horner's syndrome related to IV injection of xylazine, the neurologic signs often are irreversible, even if the primary cause of the condition has been eliminated. When xylazine is administered IV, the condition disappears spontaneously. The situation differs from inadvertent perivascular drug injections, in which permanent neurologic sequelae may occur. The necrotizing effects of perivascular drug injections can be minimized if treatment is administered immediately. These treatments should include aseptic infusion of large volumes of saline at the perivascular injection site and systemic administration of NSAIDs or dexamethasone, or both. Abscesses should be drained, and fungal infections of the guttural pouch should be treated as described in Chapter 31.

35.20 GUTTURAL POUCH MYCOSIS, NEUROLOGIC SIGNS (DAMAGE TO CRANIAL NERVES IX THROUGH XII)

35.20.1 Definition and Etiology

In one retrospective survey, mycotic infections of the guttural pouch were the third most common disease of the upper respiratory tract of horses.[1621] The clinical signs occur because fungal infections in the medial part of the pouch extend dorsally and damage CNs IX through XII and the internal carotid artery. Mycotic guttural pouch infection usually occurs in older animals; however, horses as young as 3 months have been affected.[1622]

35.20.2 Clinical Signs

Initially the horse may display head shaking and unilateral nasal discharge. Additional clinical signs are nasal catarrh, dysphagia, head shyness, head shaking, roaring, dysphonia, protrusion of the tongue from the mouth, and epistaxis[1622–1624] (Fig. 35-21). Other clinical signs include parotid pain, abnormal head posture, facial sweating, shivering, Horner's syndrome, colic, hemiparesis to hemiplegia of the tongue on the affected side, and facial paralysis.[1622–1628] Epistaxis may be fulminant and life threatening. The abnormal head posture is characterized by a tendency to hold the head in extension or lower to the ground than normal. Atrophy of the brachiocephalicus and trapezius muscles occurs secondary to denervation of the accessory spinal nerve. Horner's syndrome occurs secondary to damage of the cranial cervical ganglion and sympathetic trunk. The sensorium is intact unless aspiration pneumonia develops or the fungus embolizes into the brain.[1629,1630] Occasionally, affected horses die peracutely as a result of exsanguination from a ruptured internal carotid artery. Endoscopic examination of the larynx of affected horses may reveal dorsal displacement of the soft palate, inability to swallow, and unilateral or bilateral laryngeal hemiplegia. Mycotic guttural pouch infection can be definitively diagnosed by endoscopically identifying the characteristic fungal mass in the dorsomedial compartment (Fig. 35-22). Radiographic examination of the pouches shows a poorly defined border of the pouch in the abnormal area. Extension of a mycotic infection from the guttural pouch to the brain through the internal carotid artery has been reported.[1630] The infection caused disseminated necrosis and hemorrhage that

was most severe in the thalamus, cerebral cortex, and hippocampus. The clinical signs were fever (38.3° C; 100.9° F), epistaxis, dysphagia, laryngeal hemiplegia, pharyngeal paralysis, circling, unilateral blindness, mydriasis, facial paralysis, and apprehension.

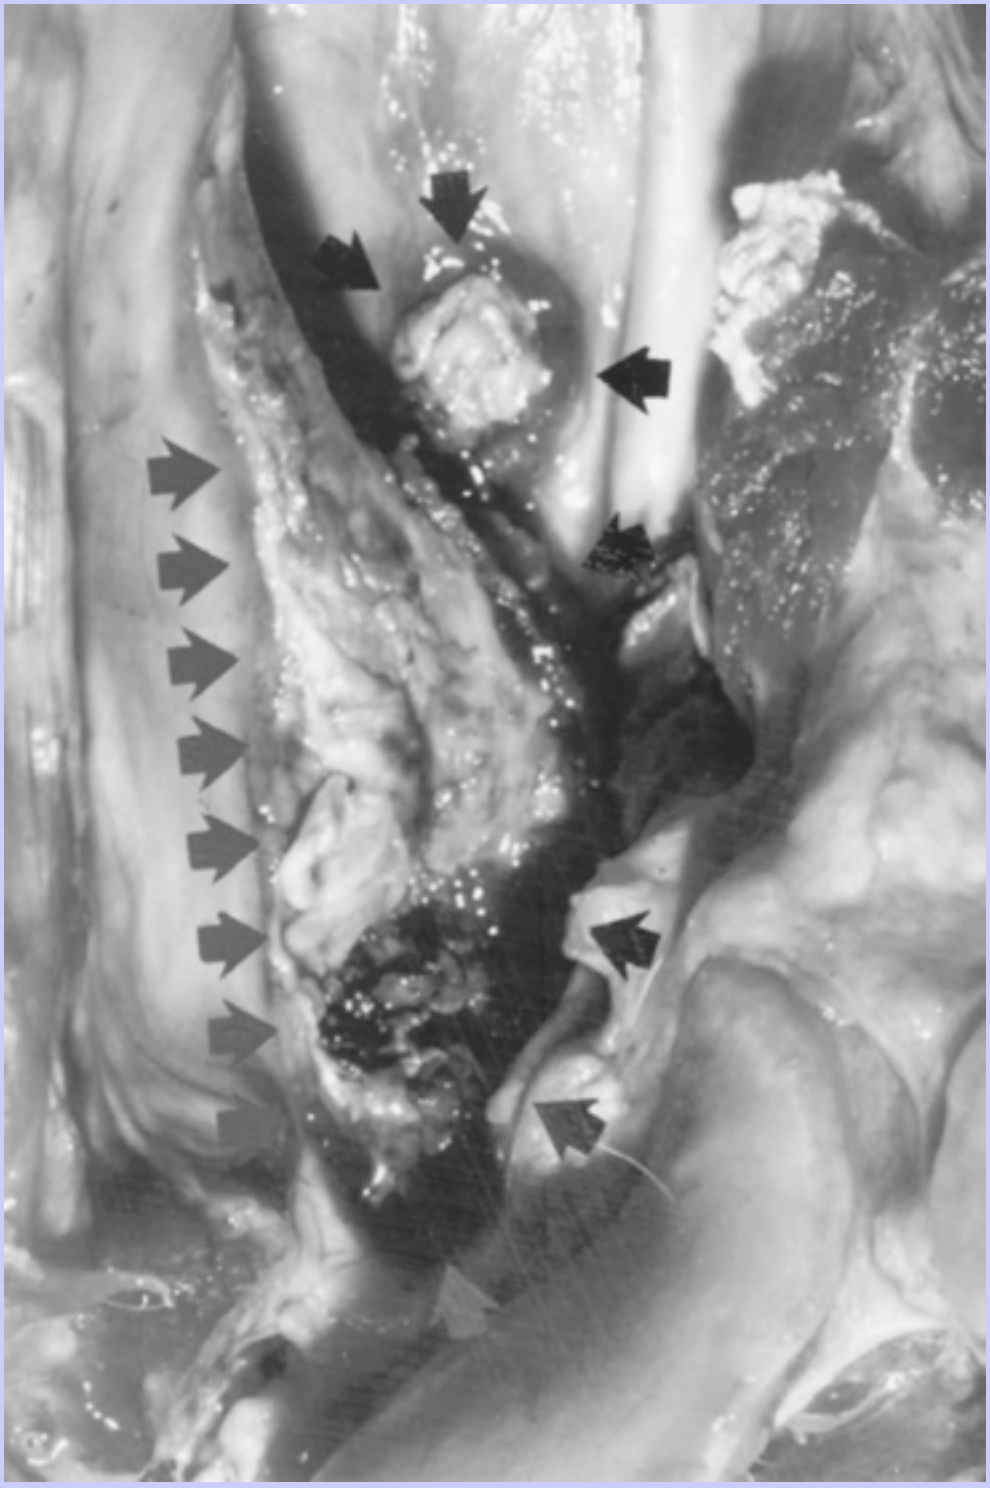
Fig. 35-21 Regurgitation of food material from the nose of a dysphagic horse with pharyngeal paralysis. The horse had a mycotic infection of the guttural pouch.

35.20.3 Pathophysiology

The guttural pouch is separated into two compartments by the stylohyoid bone and the occipitohyoideus muscle. CNs IX through XII and the internal carotid artery are located in the dorsomedial aspect of the medial compartment and are susceptible to damage from mycotic infections. Extension to the cranial nerves occurs because of inflammation and direct destruction of these structures by the fungal elements. Pathologic studies have shown swelling of the myelin sheaths and Schwann cells. Some sections demonstrate necrosis of the nerves and invasion by fungal elements.[1631]

In chronic infections the fungal lesion may extend into the tympanic bulla and cause vestibular disease. Extensive growth of the lesion also results in temporomandibular osteoarthropathy and fusion of the temporomandibular joint or osteoarthritis of the atlantooccipital joint. Excessive muscular force on the fused joint can result in avulsion fractures of the petrous temporal bone and calvarium. Hemorrhage or spread of infection into the vestibular apparatus and calvarium results in acute vestibular disease, cerebral hemorrhage, and septic meningitis (see Peripheral Vestibular Disease of Horses). In rare cases, fungal elements may reach into the lateral compartment, invade the wall of the internal maxillary artery, and affect the facial nerve. Facial nerve paralysis also has been observed and results from abscessation of the parotid lymph nodes secondary to a fungal guttural pouch infection.[1623] In other rare cases, Horner's syndrome may be caused by mycotic lesions in the cranial cervical ganglion. The syndrome also may occur iatrogenically during surgical ligation of the external carotid artery.[1632] Occasionally, the mycotic infection may extend into the brain and cause encephalitic signs.[1629]

Fig. 35-22 Appearance of a mycotic lesion in the dorsomedial compartment of the guttural pouch. Arrows outline the mycotic plaque.



35.20.4 Treatment

Before the onset of neurologic disturbances, the internal carotid artery may be occluded using a ligature or by insertion of a balloon-tipped catheter.[1633] During the exploration the fungal mass is debrided surgically. The surgical procedure is effective for preventing fatal epistaxis but may not reduce the potential for progression of the infection, resulting in nerve deficits or extension of the infection to the CNS. Some studies have shown excellent resolution of the mycotic lesion in horses that underwent carotid artery occlusion with or without additional antifungal therapy,[1634–1636] but in other animals the lesion may progress despite complete arterial occlusion.[1628] Moreover, optic neuropathy and blindness of the ipsilateral eye are common postsurgical sequelae.[1637] Neurologic signs may be permanent, although improvement or recovery over many months has been reported in some horses.[1636] Affected horses often are euthanized for humane reasons. (See Chapter 31 for treatment of guttural pouch mycosis.)

35.21 DISEASES PRODUCING TREMORS AND ATAXIA; CEREBELLAR DISEASES

35.21.1 CEREBELLAR HYPOPLASIA CAUSED BY CONGENITAL BOVINE VIRAL DIARRHEA VIRUS INFECTION

A complete discussion of bovine viral diarrhea–mucosal disease (BVD-MD) can be found in Chapter 32. BVD virus infection of susceptible pregnant cattle from 90 to 170 days' gestation results in abortion or stillbirth, hydranencephaly, or cerebellar hypoplasia in the fetus.[1638,1639] These signs are also seen in calves born to susceptible dams vaccinated during gestation with a modified live BVD vaccine.[1640] The BVD virus infects the developing germinal cells of the cerebellum and kills Purkinje's cells in the granular layer, resulting in necrosis and inflammation.[1641] Such cerebellar lesions tend to be most severe by 21 days after inoculation of the susceptible pregnant dams.[1638] The microscopic lesions include necrosis of the external germinal cells, focal parenchymal hemorrhages, and folial edema. After infection the acute inflammatory responses subside by 42 days, when the microscopic changes include cavities ranging from 1 to 7 mm in diameter, thinning of the neuropil, atrophy of the cerebellar folia, axonal torpedoes, and mild reactive astrocytosis. Calves infected with vaccine virus between 90 and 118 days' gestation may develop hydrocephalus and hydranencephaly.[1642]

The signs of cerebellar dysfunction usually are present at birth and include truncal ataxia, falling backward, opisthotonos, base-wide stance, coarse intentional head tremors, hypermetria, hyperreflexia, and nystagmus or strabismus (Fig. 35-23).[1643,1644] If severely affected, the animal may be unable to stand or lie in sternal recumbency. Excitatory stimuli in these animals precipitate wild oscillations and side-to-side movements of the head, which can be mistaken for convulsions. The affected calves may have a deficient menace response and appear to be blind, especially with concomitant hydranencephaly or microphthalmia. The neurologic condition rarely improves after birth. Other fetal changes that may be induced by the BVD virus include thymic atrophy, retinal degeneration, corneal opacity, failure to grow, and abortion.[1638,1643] The diagnosis of cerebellar hypoplasia is based on identification of the specific clinical signs and the recognition of BVD antibodies in precolostral blood specimens. The virus may be cultured from the blood of some affected calves. Viral antigen has been detected in the spleen, kidneys, and lymph nodes of aborted fetuses.[1644] The virus cannot usually be isolated from immunocompetent calves after antiviral antibody responses develop but may be recovered

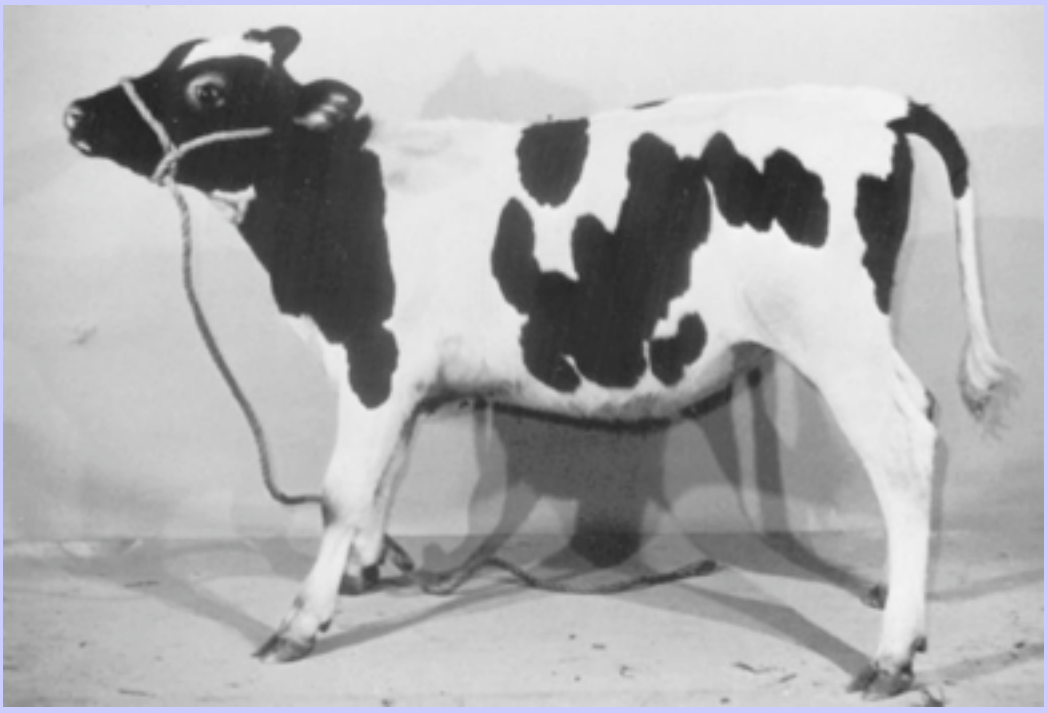
repeatedly from immunoincompetent, seronegative calves. Bluetongue virus may also occasionally cause cerebellar lesions in calves and lambs.

Fig. 35-23 Characteristic head position and base-wide stance of a calf with cerebellar hypoplasia.

35.22 CEREBELLAR ABIOTROPHY OF CATTLE

Abiotrophy is defined as a degeneration of formed elements of the nervous system.[1645] Cerebellar abiotrophy has been described in Holstein, Angus, and Limousin calves. The condition has been reported in the United States, Canada,[1646–1648] Australia,[1649,1650] and the United Kingdom.[1651] In Holstein calves a recessive mode of inheritance is suspected, which can be traced to a single sire. The etiology of the condition in other breeds of cattle is uncertain. Some calves are affected from birth,[1651] whereas others are normal at birth but develop signs at 3 to 9 months, or show signs intermittently, especially when stressed by factors such as inclement weather.[1649,1650] Severely affected animals may be in lateral recumbency and unable to rise. Nystagmus and opisthotonos are often seen in these calves. During the physical examination, signs of cerebellar dysfunction may be observed (Fig. 35-24), including intentional head tremors, base-wide stance, hypermetria, hyperesthesia, hyperreflexia, and lack of menace with preservation of eyesight. The clinical condition of affected animals may remain static or progress slowly until the animals become recumbent and unable to rise. Two calves showed gradual resolution of clinical signs when moved to a new location[1650]; thus environmental factors may play some role in the clinical development of the disease. The pathophysiology of the disease is unknown. There are no macroscopic abnormalities of the cerebellum of affected calves. The microscopic pathologic changes of abiotrophy include noninflammatory focal loss of Purkinje's cells and cerebellar nuclear neurons, with gliosis in the Purkinje and molecular cell layers. Swellings within Purkinje cell axons also have been described in some cases.[1650] The variable pathology described in affected animals suggests that bovine cerebellar atrophy may be several similar but slightly differing disorders rather than a single entity.

Fig. 35-24 Characteristic head posture and stance of a calf with cerebellar abiotrophy. Courtesy Dr. R.H. Whitlock.



35.23 HEREDITARY HYPERMETRIA IN SHORTHORN CATTLE

A neurologic disease characterized by symmetric cerebellar signs was reported in 15 shorthorn cattle of Brazil. The animals were affected at birth, and the clinical disorder was not progressive. The affected animals had no pathologic changes in the central nervous system that differentiated the condition from cerebellar hypoplasia and cerebellar abiotrophy. Examination of the relatives of the affected animals indicated a familial distribution. Pedigree analysis suggested an autosomal recessive mode of inheritance.[1652]

35.24 CEREBELLAR MALFORMATIONS OF AYRSHIRE AND JERSEY CALVES

Cerebellar malformations have been reported in two Ayrshire calves from Great Britain.[1653] The calves appeared to be normal at birth but displayed characteristic signs of cerebellar dysfunction by 24 hours of age. A similar condition has been reported in Jersey calves.[1654,1655] The clinical signs included opisthotonos, base-wide stance, truncal ataxia, hypermetria and hypertonia of all four limbs, and head tremors. Lesions in the calves were present in the cerebellum and the pons; some animals also developed hydrocephalus. The cause of these abnormalities was not definitely determined but was presumed to be a hereditary condition. The relationship of this disease to BVD virus infection is unclear.

35.25 BOVINE FAMILIAL CONVULSIONS AND ATAXIA

Bovine familial convulsions and ataxia is a disease of Angus cattle characterized by multiple tetanic tonic-clonic convulsions and a spastic ataxia that persists for several months.[1656–1658] A similar condition has been reported in a 9-month-old Charolais calf in the United States, in polled Hereford calves in Australia, and in Angus crossbred calves in Canada.[1659–1661] The disorder is believed to result from a defective autosomal dominant gene with incomplete penetrance, although some affected animals did not have a close relationship to blood lines believed to carry the trait.[1658]

35.25.1 Clinical Signs

The onset of clinical signs ranges from 2 to 3 hours after birth to 3 months of age. Calves may be born dead at or near term or may be aborted. Some aborted calves have a dorsiflexion of the spine. Most affected calves are born alive and rapidly develop intermittent signs of cerebellar dysfunction with multiple “tetaniform seizures” that last 3 to 12 hours. Two forms of seizures have been described. One form is characterized by a generalized stiffness and inability to protract the legs, elevation of the tailhead, and head-neck extension with mild head tremor. The animals are hyperesthetic. A more severe form is characterized by lateral recumbency, loss of consciousness, opisthotonos, hypertonicity, tonic-clonic seizures, and trismus. Animals may improve greatly if supported during the tetaniform activity. The frequency of the seizures declines over several months, but animals are left with a permanent ataxia characterized by cerebellar signs. The attacks may be precipitated by sudden, violent auditory, olfactory, visual, or tactile stimuli. These could include driving by dogs, shipment, flashing lights, loud sounds, or painful tactile stimulation. These features of the attacks, combined with a lack of electroencephalographic (EEG) evidence of seizure activity in the cerebrums of affected calves, suggest that these episodes may be exacerbations of cerebellar signs rather than true seizures.[1662] There is no response to treatment with electrolytes, mineral supplements, or B-complex vitamin injections. Seizure-like activity can be controlled by administration of barbiturates or inhalational anesthetics.

Most animals improve when turned out to grass pastures, but episodic relapses associated with excitement may occur for as long as 2 years. Affected animals gradually recover and by 2 years of age either show only mild cerebellar signs or are completely normal. There are no specific diagnostic tests for the disease.

35.25.2 Pathology

The gross appearance of the brain is normal. Microscopic lesions are restricted to the cerebellar cortex and include swelling and vacuolation of Purkinje's cells, chromatolysis, loss of neurofibrils, and formation of axonal torpedoes. The axonal structures have been defined as “argyrophilic axonal swellings.” They are located in the granular layer of the lingula, uvula, and adjacent parts of the vermis. An early report stated that these lesions were not seen in affected animals under 6 weeks of age, but a more recent study found lesions in affected animals of all ages.[1661,1663]

35.25.3 Diagnosis

Diagnosis is based on the presence of typical clinical signs, particularly when several related animals are affected. Differential diagnoses include cerebellar hypoplasia caused by congenital BVD virus infection, hypomyelinogenesis, congenital brain malformations affecting structures in the caudal fossa, congenital storage diseases, and the various cerebellar abiotrophies described in cattle.[1662] Imaging studies (e.g., CT, MRI) are expected to be within normal limits.[1662] Definitive diagnosis can be made only on histologic examination postmortem.

35.25.4 Treatment and Control

There is no known treatment for bovine familial convulsions and ataxia. Affected animals can be fattened and slaughtered but should not be used as breeding stock because the disease is genetically transmitted. Elimination of carrier animals from the breeding population will effectively control the propagation of this disease.

35.26 CEREBELLAR ABIOTROPHY (HYPOPLASIA) IN ARABIAN HORSES

Cerebellar abiotrophy occurs in purebred Arabian or Arabian crossbred horses.[1664–1669] Clinical signs may be present at birth or may develop after several weeks to months of postnatal life. Signs most frequently develop between 2 and 4 months of age and almost always occur before 6 months of age. The disease was initially reported as a cerebellar hypoplasia, but most descriptions suggest that the degeneration begins postnatally, prompting classification of the condition as an abiotrophy.[1670] Some investigators have suggested, however, that the clinical and pathologic course of the disease is not always consistent with a progressive postnatal degeneration of the nervous system.[1666]

The signs of cerebellar abiotrophy appear suddenly and range from subtle ataxia to complete diffuse cerebellar dysfunction. Head tremor is usually present and may occur in either a vertical or horizontal direction. Some horses show no progression of signs, whereas others progress slowly, followed by a plateau. The initial clinical sign in most foals is mild conscious proprioceptive deficits. As the deficits worsen, affected animals show hypertonia and stiff, hypermetric gaits accentuated by stimulation. In the most severe cases the animal may rear and fall over backward when suddenly startled. More severely affected foals have marked intentional head tremor, truncal ataxia, and hypermetria of all four limbs, often more pronounced in the forelimbs. These deficits are exaggerated

by turning the animal sharply, by having the foal step up and down a curb, or by walking the foal on an incline. Most affected animals have a decreased to absent menace response despite normal visual acuity and facial nerve function; however, two affected foals with normal menace responses have been described.[1665,1667] Rotary nystagmus occurs in rare cases.

Diagnosis generally is made on the basis of typical clinical signs in an Arabian horse under 6 months of age. Differential diagnoses include head trauma (particularly associated with basisphenoid bone fracture) and atlantooccipital malformation. With head trauma, other evidence of trauma and signs of vestibular dysfunction often are present. Foals with atlantooccipital malformation are ataxic and somewhat weak but do not have intentional head tremors. Muscular strength is preserved in cerebellar abiotrophy. Cerebrospinal fluid (CSF) analysis usually is normal, although CSF creatine kinase occasionally is elevated.

The major histologic finding is a degeneration and loss of Purkinje's cells in the cerebellum accompanied by gliosis and thinning of the molecular and granular layers of the cerebellum. Evidence indicates that apoptosis may be the primary mechanism underlying Purkinje cell death in Arabian horses with cerebellar abiotrophy.[1671] Mineral deposits in the thalamus also are found in horses with cerebellar abiotrophy, but their significance and relationship to the cerebellar changes are unknown.[1669]

The cause of cerebellar hypoplasia in Arabians is unknown, but there is a familial pattern of occurrence. One survey has reported an 8% prevalence rate in one family of 36 foals and a 6% rate in another family of 67 foals.[1664] Two of four full-sibling colts from a mare were affected.[1664] Pedigree analysis of 19 affected animals showed a high degree of relationship between the patients.

No effective treatment exists for cerebellar abiotrophy of Arabian foals. Occasional animals are reported to have shown gradual mild improvement, with considerable resolution of the head tremor. They remain unsafe for riding, however, and are not suitable as breeding stock because the disease probably is inherited. Owners of affected foals should be counseled about the probable heritability of the disease and should be encouraged to discontinue use of the parent lineage as breeding stock.

35.27 FAMILIAL ATAXIA IN HEREFORD CALVES

A central nervous system (CNS) disorder characterized by lateral recumbency, ataxia, incoordination, pupillary dilation, and abnormal head posture has been reported in Hereford calves.[1672] The disease occurred at 24 hours of age. The pathologic lesions could be differentiated from those of hereditary neuraxial edema and familial convulsions and ataxia of Angus cattle. The lesions in the Hereford calves included hypomyelination of the cerebellum, cerebral cortex, medulla, and midbrain and vacuolation of the white matter. No necrosis of the CNS or inflammatory lesions was seen, and the neurons of the cerebellum appeared to be normal. The cause of the condition was not identified, but the dams were highly related, and a genetic etiology was postulated.

35.28 MICROGNATHIA AND CEREBELLAR HYPOPLASIA IN ANGUS CALVES

Micrognathia was observed in Angus calves of a small herd in western Missouri. These animals were born dead. The calves had severe brachygnathia and cerebellar hypoplasia. Other somatic changes included hepatomegaly and patent foramen ovale. A pedigree analysis indicated that an autosomal recessive genetic trait derived from a common ancestor may have been responsible for the condition.[1673]

35.29 STORAGE DISEASES AND INBORN ERRORS OF METABOLISM

Storage diseases and inborn errors of metabolism are characterized by intraneuronal accumulation of indigestible metabolic products. The material accumulates in the cells because of a deficient activity of one of several lysosomal catabolic enzymes. Neurons have a long lifespan and are rich in gangliosides and glycolipids, which are continuously degraded and resynthesized. In normal animals the metabolic products are internalized by the intraneuronal lysosomes and are degraded into constituent amino acids, monosaccharides, fatty acids, alcohols, and simple lipids by acidic catabolic enzymes. Disturbances of ganglioside metabolism result in accumulation of the degraded by-products in the neurons and other cells.[1674] Overloading of the lysosomes by the undigested material produces profound neurologic dysfunction.

Storage diseases can be classified as either genetic or acquired. Acquired storage diseases are caused by ingestion of plants that contain specific inhibitors of one or more lysosomal catabolic enzymes. Genetic storage diseases are caused by the production of an inactive lysosomal enzyme. One such storage disease is ceroid lipofuscinosis, described earlier.

The genetic storage diseases are named according to the metabolic by-product that accumulates in the lysosomes. When tissues of affected animals are sectioned, processed, and examined microscopically, the metabolic storage product is dissolved from the tissue sections by the normal dehydrating and fixative agents. The spaces that contain the product appear as intraneuronal vacuoles when examined by light microscopy. Special fixation and staining procedures may be used to preserve and identify the metabolic product.[1674]

35.30 α-MANNOSIDOSIS (PSEUDOLIPIDOSIS)

α-Mannosidosis is a genetic defect of the enzyme α-mannosidase that is inherited as an autosomal recessive trait in Angus, Murray Gray, Simmental, Galloway, and Holstein cattle.[1675] At least two different mutations in the gene coding for α-mannosidase occur in different breeds of cattle and have been characterized in Angus and Galloway breeds.[1676] In animals deficient in α-mannosidase, the final cleavage between *N*-acetylglucosamine and mannose cannot occur, and the oligosaccharide accumulates in the lysosomes of the macrophages, neurons, and reticuloendothelial cells.[1674] Other abnormalities of glycoprotein metabolism occurring in affected animals may be the result of the multiple functions that have been ascribed to α-mannosidases.[1677]

The clinical signs first appear by 1 week to 15 months of age. Affected calves tend to be less well developed than age-matched herdmates.[1678,1679] The first symptom usually is a mild ataxia of the pelvic limbs that develops after exercise. Other signs include mild intentional head tremor, hypermetria, base-wide stance, and unwarranted aggressiveness.[1678] When galloping, the rear limbs are overflexed, and the animal's hindquarters appear to be sunken. The nervous system signs become much worse when the animals are excited. Most patients develop diarrhea, become recumbent after 3 to 4 months, and die shortly thereafter. A few affected animals survive for as long as 4 years. The neurologic signs of these animals remain constant, but they usually fail to grow normally. Other clinical manifestations in calves include premature delivery, abortion, stillbirth, and superior brachygnathia. Mannosidosis in Galloway calves is associated with somatic abnormalities such as arthrogryposis, hydrocephalus, and hepatic and renal enlargement.[1675,1680] Phenotypic variations affect the severity and onset of the neurologic signs.

The concentration of α-mannosidase in the plasma can be measured with an enzymatic assay. Heterozygotes have less activity than genetically normal animals; however, occasional overlapping between the phenotypes of homozygotes and heterozygotes can confound attempts at classification. Three isoenzymes of α-mannosidase exist, but only one form is inactive in diseased animals. A delay in separation of the plasma from the cells or the use of serum for enzymatic assays results in a leakage of other isoenzymes from tissue compartments and uncertainty in interpretation of the results. In most cases, two populations of animals usually are evident, the homozygous normal and the heterozygote. The mean plasma concentration of α-mannosidase in heterozygotes is 6.6 nmol/min/mL, whereas the mean plasma enzyme activity in homozygotes is 29.1 nmol/min/mL. The test is most accurate at detecting heterozygotes over 18 months of age.

The brain enzyme activity of heterozygotes ranges from 0.03 to 0.05 IU/g of tissue; the reference range of enzyme activity is 1.8 to 3.1 IU/g. Heterozygotes also may be detected by measuring the relative concentration of α-mannosidase and hexosaminidase in purified peripheral blood neutrophils. This test has been recommended for confirmation of a carrier animal whenever the plasma mannosidase assay is questionable.

35.30.1 Pathology

The diagnosis of a clinical case of mannosidosis can be substantiated pathologically by observation of cytoplasmic vacuolation in the neurons of the cerebrum, cerebellum, brainstem, and spinal cord.[1675] There is also a mild to marked internal hydrocephalus. The microscopic appearance of the brain of affected calves is characterized by vacuolation of the neurons and astrocytes and by reactive astrocytosis.[1675] The vacuolation is not restricted to the nervous system, however, and can be seen in Kupffer's cells, pancreatic exocrine cells, fibrocytes, and macrophages of the spleen and lymph nodes.[1681] The vacuoles are lined by a single membrane and are thought to be part of the Golgi apparatus.[1681] Associated neuronal changes include axonal swelling and spheroids.

Because of the hereditary nature of the disease, the ancestry of affected animals should be traced, and the biochemical phenotypes of related individuals should be tested. Both biochemical and molecular testing facilitate early detection of carrier animals, enabling their elimination from breeding programs.[1682] Although bone marrow transplantation has been shown to correct the defect in the feline and murine models of α-mannosidosis,[1683–1685] there is currently no effective and practical treatment for α-mannosidosis of cattle.

35.31 β-MANNOSIDOSIS

β-Mannosidosis is an autosomal recessive genetic trait of Anglo-Nubian goats and Salers calves. Mannosidosis in goats has a worldwide distribution, with reported cases occurring in Australia, Canada, and the United States.[1686–1690] The frequency of the condition is estimated at 1 in 2000 births of purebred Salers calves. The disease is seen in both the red and the black phenotype of Salers. The gene encoding for β-mannosidase has been characterized in both cattle and goats.[1691,1692] A single base mutation in the complementary DNA (cDNA) coding for the enzyme results in premature termination of translation. PCR-based tests have been used to identify β-mannosidosis carriers of both species.[1692,1693]

1058 1059

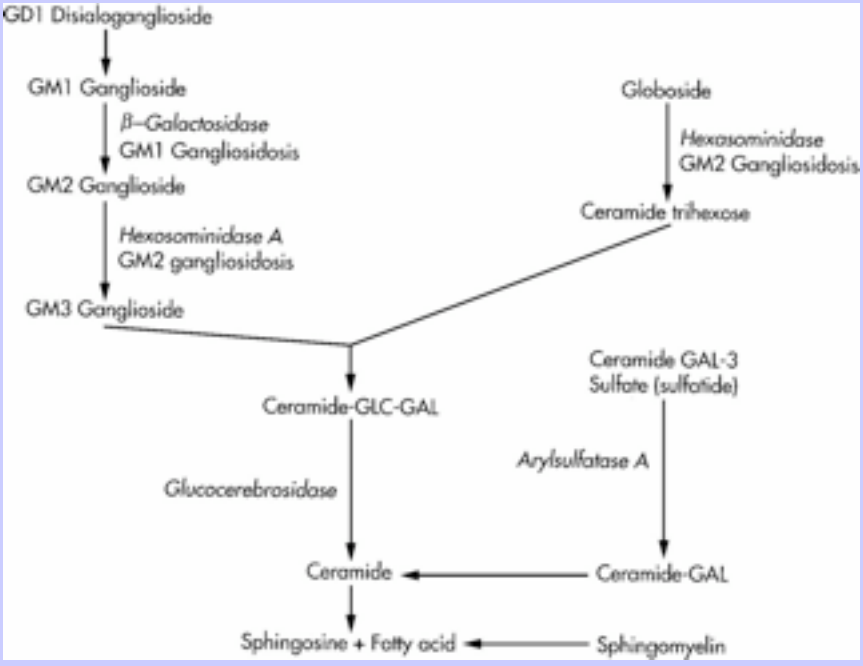
The lesions of mannosidosis have been identified in aborted fetuses and fetuses in utero, and clinical signs are often present at birth.[1694–1698]

The clinical signs in goats include recumbency at birth, deafness, shortened sternum, narrowed palpebral fissures, decreased muscle mass, intentional head tremor, carpal contractures, pastern joint hyperextension, thickened skin, shortened head, excessive gingival tissue, short curled ears, and domed skull.[1686,1699] Numerous ocular changes are seen, including pendular nystagmus, ventrolateral strabismus, thickened immovable eyelid, hazy vitreous humor, ptosis, and Horner's syndrome.[1700] The head movements are described as wide circular motions that culminate with the animal in lateral recumbency. Pupillary and corneal reflexes are intact, and the affected animals appear to have some vision. Compared with goats, affected calves respond to aural and visual stimuli. Other neurologic abnormalities include recumbency, depression, loss of suckle reflex, spontaneous chewing activity, head tremors, depression, and nystagmus.

The diagnosis of β-mannosidosis is based on observation of characteristic microscopic lesions in the central nervous system (CNS), demonstration of decreased tissue β-mannosidase activity, and demonstration of mannose-based oligosaccharides (Nanβ1-4G1cNAc and Manβ1-4G1cNAcβ1-4G1cNAc) in the CNS.[1701] The concentration of serum thyroid hormones is decreased.[1702] Some affected calves have concomitant colisepticemia or bovine viral diarrhea (BVD) infection.

In contrast to α-mannosidase, β-mannosidase has no isoenzymes.[1703] The mean concentration of β-mannosidase in the plasma of normal goats ranges from 66 to 222 nmol/hr/mL of plasma.[1695] There is no detectable β-mannosidase activity in the plasma of affected goats, and the activity in heterozygotes is intermediate between these ranges. The plasma concentrations of β-mannosidase in heterozygotes range from 43 to 64 nmol/hr/mL. These tests cannot be interpreted rigidly because there is significant variability among assays, storage conditions, and different age-groups of cattle.[1690]

Fig. 35-25 Catabolic pathways for gangliosides. Relevant enzymes and diseases caused by enzyme deficiencies are *shown in italics*.



In addition to the CNS abnormalities, cardiomegaly, thyromegaly, and pathologic fractures have been described in affected goats. Calves show a cerebral ventricular dilation and green discoloration of the renal cortices. Microscopic pathologic changes in the CNS include hypomyelination, axonal spheroids, and foamy-appearing neuronal cytoplasm.[1703] The heat shock protein ubiquitin has been detected in the CNS of affected calves.[1704] Cytoplasmic vacuolation also is present in the visceral organs.[1705,1706] Although in utero bone marrow or stem cell transplantation may offer hope for alleviation of the disease in the postnatal animal, no practical treatment exists for animals with β-mannosidosis.[1698]

35.32 GENERALIZED GLYCOGENOSIS (GM1 GANGLIOSIDOSIS; β-GALACTOSIDASE DEFICIENCY)

Generalized glycogenosis is a rare heritable defect of Holstein cattle and several breeds of sheep.[1707–1712] Generalized glycogenosis results from deficient activity of β-galactosidase, resulting in accumulation of the GM1 ganglioside, asialo-GM1, and neutral long-chain oligosaccharides in the tissues[1708] (Fig. 35-25).

A combined deficiency of β-galactosidase and α-neuraminidase has also been described.[1713] This condition is thought to result from a defect of the structural gene of β-galactosidase. The loss of α-neuraminidase occurs because of an inability of the βα-galactosidase molecule to dimerize with α-neuraminidase, leading to deactivation of both molecules.

The clinical signs of all forms of β-galactosidase deficiency are similar. Affected animals tend to show lethargy and anorexia by 1 month of age. The head and neck are held low and rigidly extended. The animals are depressed, stiff, and ataxic, have a base-wide stance, appear to be blind, and eventually become recumbent. The animals tend to fall whenever the head is moved. The blindness is the result of dysmyelination in the optic nerve, which can be detected by observation of numerous small white spots on the retina. None of these signs are pathognomonic for the disease, so biochemical testing or lectin histochemistry to characterize the stored carbohydrates in affected cells is needed for specific diagnosis.[1714,1715]

The genetic disorder is thought to be caused by an autosomal recessive gene. A biochemical test for β-galactosidase using centrifugally purified bovine neutrophils has been described.[1708] Animals with fewer than 3 IU of heat-stable activity are considered deficient. In herds in which GM1 gangliosidosis has already been substantiated, observation of slowness in feeding and lack of alertness has proved to be diagnostically significant.

Pathologic changes of GM1 gangliosidosis are present in the fetus as well as postnatally and include neuronal enlargement, vacuolation, accumulation of granular material in the nerve cells, spheroids, and loss of neurons without gliosis.[1716,1717] The material stains strongly with periodic acid–Schiff (PAS)/alcian blue, Sudan black, and oil red O. The vacuolar contents are composed of complex lipopolysaccharides, including β-galactose, *N*-acetylneuraminic acid and *N*-acetylgalactosamine.[1718]

No treatment is currently available for this disease. Strategies such as in utero bone marrow transplantation or stem cell transplantation may hold promise for the future, but are unlikely to become a viable option in large animal species.[1719]

35.33 BOVINE GENERALIZED GLYCOGENOSIS (TYPE II GLYCOGENOSIS; POMPE's DISEASE)

Generalized glycogenosis results from a dysfunction of α-glucosidase. The condition occurs in shorthorn and Brahman cattle[1720–1722] and is controlled by a single recessive allele.[1723] Several different mutations are described within the bovine α-glucosidase gene and are specific to the breeds.[1724] Two separate clinical entities have been described: the cardiac (infantile) form and the late-onset form. Clinical signs of the infantile form are first seen at about 2 to 3 months of age and include growth failure, weakness, hyperesthesia, muscle tremors, ataxia, conscious proprioceptive deficits, and recumbency.[1723] The cardiac (infantile) form is characterized by right-sided heart failure at 3 to 5 months of age. Brahman calves with the late-onset form die at age 8 to 9 months, whereas affected shorthorn calves may survive for more than a year. The tissues of affected cattle contain only 2% to 5% of the normal α-glucosidase activity.[1723,1725] The concentration of glycogen in the liver and muscles is increased.

The pathologic lesions of the CNS in both forms are similar to those of cattle with α-mannosidosis, including cytoplasmic swelling and foamy cytoplasm in the CNS neurons. Lesions are found in the myocardium and skeletal muscle. These include vacuolation and swelling of Purkinje's cells and myofibers.[1726] Because of a gene dilution effect, the activity of α-glucosidase in peripheral blood lymphocytes can be used to detect asymptomatic heterozygotes.[1727] However, the test result may be falsely positive if the animals are ingesting seeds of *Castanospermum australe* (Moreton Bay chestnut trees). The seeds of this tree have an α-glucosidase antagonist. Hematopoeitic chimerism in twin animals, on the other hand, can result in normal levels of enzyme activity in animals that are heterozygote carriers for the disease.[1728] Enzymatic methods for detecting carriers have now been superseded by DNA testing of leukocytes or hair root samples.[1729]

35.34 GLOBOID CELL LEUKODYSTROPHY (KRABBE'S DISEASE)

Globoid cell leukodystrophy has been reported in polled Dorset sheep.[1730] The genetic defect is the result of a lack of galactocerebrosidase, which produces a high concentration of galactocerebroside in myelin. The clinical signs are seen by 4 months of age. Affected animals show depression, hypersensitivity, conscious proprioceptive deficits, slight tremor of the head and neck, exaggerated patellar reflex, incoordination, and tetraplegia. The activity of the tissue galactocerebrosidase can be measured to substantiate the clinical diagnosis. Differential diagnoses include other heritable disorders, such as neuropathy and abiotrophy of the cerebellum and swainsonine (locoweed) toxicity (see later).[1731]

35.35 NEURONAL LIPODYSTROPHY

Neuronal lipodystrophy occurs in Angus and Beefmaster calves and in sheep.[1732–1734] The biochemical lesion of the condition is unknown. The clinical signs are first seen at about 10 months of age and include depression, blindness, ataxia, circling, coma, and tonic-clonic convulsions. The pathologic lesions include neuronal vacuolation with eosinophilic and sudanophilic inclusions. The inclusions are cytoplasmic and perinuclear and are located in the axonal and dendritic zones. As with other neurovisceral storage diseases, the inclusions are bound by a single membrane. Involvement of the spleen and lymph nodes also can be demonstrated. The mode of inheritance is unknown. There is no effective treatment for the disease.

35.36 SHAKER CALF SYNDROME

Shaker calf syndrome is an inherited neurodegenerative disorder of newborn horned Hereford calves.[1735] The condition is characterized by recumbency, fine tremors of the neck and hindlimbs, and hypermetria. The amplitude and frequency of the tremors are increased by stimulation. Other clinical signs include aphonia, loss of fine motor control of the tongue, hyperesthesia, exaggerated spinal reflexes, and hypertonia. Most affected calves die of starvation by 5 days of life; however, one case of remission followed by relapse after 2 weeks has been described. The cause of the disease is unknown. Limited breeding trials indicate a 12.5% inbreeding factor in affected calves, suggesting a hereditary etiology. The pathologic lesions include a neurofilamentous neuronal degeneration of multiple cell groups of the central nervous system (CNS) and of ganglion cells of the peripheral and autonomic nervous systems. The spinal cord is most severely affected. Neuronal degenerative changes include distention of axons and dendrites by a faintly fibrillar material, neuronophagia, and reactive gliosis. Wallerian degeneration of the spinal rootlets, spheroids, and empty fiber tracts in the spinal cord are noted. The pathologic appearance of the tissues differs from that of calves with hereditary neuraxial edema.

35.37 MAPLE SYRUP URINE DISEASE (SPONGIFORM ENCEPHALOPATHY)

Maple syrup urine disease (MSUD) is a hereditary spongiform encephalopathy characterized by severe CNS disturbance in newborn Hereford and polled shorthorn calves.[1736] The disease has been reported in Australia and Canada and may have occurred in the United States.[1737] The biochemical lesion is a deficiency of branched-chain 2-oxo acid dehydrogenase, which results in accumulation of the 2-oxo acids 4-methyl-2-oxopentanoate, 3-methyl-2-oxobutanoate, (S)-(S-KMV), and (R)-3-methyl-2-oxopentanoate, as well as their precursors leucine, valine, isoleucine, and alloisoleucine.[1736,1738,1739] The urine becomes highly viscous, discolored, and malodorous because of the excretion of these substances through the kidneys. The buildup of the transamination product of isoleucine, α-keto-β-methylvaleric acid, probably gives the urine the odor of burnt maple syrup. Branched-chain α-keto acids have been shown to inhibit energy production in the brain and to cause morphologic changes and death of astrocytes in vitro.[1740,1741] High levels of leucine are directly neurotoxic.[1742] Pyruvate is a vital constituent of the Krebs cycle, which is important for the production of transmitter amino acids. The CNS hyperactivity probably is related to a decrease in GABA-mediated inhibitory transmission. The genetic defect in polled shorthorns and polled Herefords has been shown to be a thymidine-to-cytidine transition in the cDNA coding for a subunit of the branched-chain amino acid dehydrogenase, resulting in a substitution of leucine for proline.[1743] PCR testing now can be used to detect both affected and carrier animals. A protocol for genotyping cattle for both MSUD and inherited neuraxial edema has been used to estimate the frequency of the alleles responsible for these diseases in Australian cattle (0.01 to 0.02).[1744]

1060
1061

Affected calves are born normal but are depressed by 2 to 3 days. They also are febrile (39.5° C to 42° C; 103.1° F to 107.6° F). They initially show ataxia and depression and become recumbent by the second to third day of life. At that time they show hyperesthesia, opisthotonos, muscular rigidity, myoclonic limb jerks, nystagmus, repetitive head tremors, stimulus-induced tetanic spasms, blepharospasm, generalized decrease of spinal reflexes, and convulsions. The urine has the characteristic color and odor reminiscent of burnt maple syrup. The calves usually die by 5 to 10 days of age. The presence of ketoacids can be detected by mixing urine with dinitrophenylhydrazine and observing a faint-yellow precipitate.[1745]

The clinical presentation of MSUD differs from that of hereditary neuraxial edema.[1737] Calves with neuraxial edema have extensor rigidity but tend to be bright and alert, whereas MSUD calves have rigid extensor tonus and

obtundation. These differential features appear to be significant because the original reports of hereditary neuraxial edema likely included calves with MSUD[1746] (see following section).

Spongiform changes caused by intramyelinic vacuolation are present in the brains of affected calves in both white matter and gray matter.[1747] MSUD can be definitively diagnosed by measuring the ratio of isoleucine, leucine, and valine to α-aminobutyric acid in fixed tissues and finding increased concentrations of these amino acids or their corresponding branched-chain 2-keto acids in urine or blood.[1747] Heterozygotes have normal blood and urine levels of both amino acids and keto acids. PCR analysis of DNA extracted from hair root samples can identify both homozygote affected animals and the clinically normal heterozygote carriers of the disease.[1748–1750] Pharmacologic dosages of thiamine are beneficial for treatment of MSUD in some human patients, probably by increasing mitochondrial thiamin diphosphate, which promotes the activity of the branched-chain α-keto acid dehydrogenase complex.[1751] However, there is no known effective treatment for MSUD in calves.[1736,1737]

35.38 HEREDITARY NEURAXIAL EDEMA (CONGENITAL MYOCLONUS; DODDLER SYNDROME)

Neuraxial edema is an inherited neurologic disease of newborn calves. Polled and horned Herefords and Hereford-Friesian crossbred cattle are affected.[1752–1759] An autosomal recessive genetic trait is thought to be responsible for the condition. The disease is well defined clinically and pathologically[1756,1759]; however, some investigators have reported a disease of polled Hereford calves that has similar neurologic signs but does not result in status spongiosus or CNS edema. These calves had a high frequency of bilateral slippage of the capital femoral epiphysis, subluxation of the femoral head, and acetabular articular cartilage fractures.[1757] The authors named the condition “congenital myoclonus” to differentiate it from hereditary neuraxial edema. Calves with congenital myoclonus have a shorter-than-normal gestational length.

The earliest reports of hereditary neuraxial edema also described two clinical forms in which some calves were bright, alert, and responsive and others had a severely depressed sensorium. Subsequent studies suggested that the calves with systemic depression probably had MSUD (see previous section) and those with normal sensorium had hereditary neuraxial edema.

The clinical signs of hereditary neuraxial edema include hyperesthesia and myoclonic discharges of skeletal musculature that occur spontaneously or in response to tactile, visual, or auditory stimuli. The calves are stillborn or are affected at birth. Affected calves are of normal size but are unable to rise; they lie quietly without lifting the head.[1752–1755] These calves develop marked extensor tonus and clonic spasms of the limbs and head when stimulated. During the spasm the animals become transiently apneic and remain dyspneic for several minutes.[1756] The spasms are less severe after repeated stimulation. Between spasms the patients can stand with assistance, but the proprioceptive responses are greatly altered, and the animals fall when support is withdrawn.[1755] The sensorium and suckling reflexes are unaltered when the calves are not in a spasmodic episode. Some authors have reported that vision and cranial nerve function are unimpaired, but others have reported nystagmus in some calves.[1752,1756] Administration of anticonvulsant drugs does not ameliorate the clinical signs. Pathologic lesions usually are not seen in the CNS of affected calves.[1753] The condition has an autosomal recessive mode of inheritance. The defect lies within the postsynaptic glycinergic receptors in the inhibitory interneurons of the spinal cord.[1760] A protocol for genotyping cattle for both inherited neuraxial edema and MSUD has been used to estimate the frequency of the alleles responsible for these diseases in Australian cattle (0.01 to 0.02).[1744]

35.39 INHERITED MYOCLONUS OF PERUVIAN PASO FOALS

Inherited myoclonus is a disorder of Peruvian Paso foals that is characterized by myoclonic contractions of the musculature in response to auditory or tactile stimuli.[1761] These contractions are sustained with repeated stimulation. Some animals are ambulatory but have a “rabbit hopping” gait. Some animals are recumbent. If assisted, the foals can rise and walk, and the animals are not depressed. Analeptic drugs and tranquilizers are ineffective for controlling this condition. Inherited myoclonus is associated with a specific deficiency of spinal glycine receptors, which are responsible for synaptic inhibition in the CNS. Glycine is a major inhibitory transmitter and works through the Ia afferent neurons in the ventral columns and the Renshaw cells. Loss of the receptors results in uninhibited synaptic transmission.

1061 1062

35.40 CONGENITAL ENCEPHALOMYELOPATHY IN QUARTER HORSES

Congenital encephalomyelopathy has been described in quarter horse foals.[1762] The condition occurred in three foals born to two different mares and three unrelated stallions. The condition was seen at birth, and clinical signs include recumbency and coarse tremors of the hindlimbs. When assisted into a standing position, the hindquarters bounced off the ground. The forelimb function appeared normal; however, the patellar reflexes were exaggerated. Affected foals are bright, alert, and responsive and have intact pain perception. There are no macroscopic CNS lesions. Microscopic lesions include spongiform degeneration and axonal swelling of the white matter of the medulla, spinocerebellar tracts, and spinothalamic tracts. The lesions extend through the entire length of the ventral funiculi of the spinal cord.

35.41 LOCOWEED POISONING (ACQUIRED MANNOSIDOSIS, *ASTRAGALUS* And *OXYTROPIS* POISONING; LOCOISM; SWAINSONINE TOXICITY; *IPOMOEA* And *SIDA CARPINIFOLIA* TOXICITIES)

35.41.1 Definition and Etiology

Chronic ingestion of a variety of different plants worldwide can result in an acquired neurovisceral storage disease. These include plants of the *Astragalus* and *Oxytropis* genera (locoweeds) in the western United States, Canada, and Australia; *Ipomoea* (shrubby morning glory) in Mozambique; the darling pea in Australia (*Swainsona* species), and *Sida carpinifolia* in Brazil (Table 35-14).[1763–1770] Horses are most susceptible to intoxication, but cattle, sheep, goats, and deer also can be affected.

Conditions that promote locoweed poisoning are hot, dry weather and a scarcity of alternative forage. Horses may be more prone to graze on locoweed than cattle, particularly when other green forage is scarce, and may increase their consumption over a single season.[1771] Chronically exposed livestock can become habituated and feed selectively on the plant over successive grazing seasons.[1772]

The following toxic components have been identified:

- Locoine, swainsonine n-oxide, and indolizidine alkaloids, which interfere with the activity of α-mannosidase and of Golgi mannosidase II.[1764,1765,1773,1774]

- β-Galactosidase and β-glucosidase.[1775]
- Aminonitrile, a compound that caused abortion and teratogenesis.
- Miserotoxin, a compound that causes a respiratory disease complex.
- Selenium accumulation (selenium toxicity may contribute to the neurotoxicity and fetal deformities).

Oxytropis and *Astragalus* plants are legumes that have herbaceous stems and alternate pinnately compound leaves. [1776] The fruits are characteristic leguminous pods that contain kidney-shaped seeds with pods marked by characteristic longitudinal grooves.[1776] The plant is eaten because it is the first vegetation available in the spring. The *Oxytropis* and *Astragalus* species found in the United States are listed in Table 35-14. Symptoms do not usually develop in cattle until 3 weeks after the animals first begin grazing the plant and may not occur until long after ingestion of the plant has stopped. The toxicity of the locoweed may vary from year to year and even within one season.[1771] Despite its relative unpalatability, some sheep may become habituated to the plant and selectively eat forage containing up to 20% *Astragalus* plants.[1772]

Table 35-14 Species of *Astragalus* and *Oxytropis* Found in Western United States

Scientific Name	Common Name
Oxytropis sericea	White locoweed, point locoweed
Oxytropis lambertii	Purple locoweed
Oxytropis campestris	Yellow locoweed
Astragalus argillophilus	Half-moon locoweed
Astragalus bisculatus	Two-grooved milk vetch
Astragalus earlei	Earles locoweed
Astragalus lentiginosus	Speckled, spotted locoweed
Astragalus mollissimus	Wooly locoweed
Astragalus mothoxys	Sheep locoweed
Astragalus wootnii	Wooton locoweed

From Knight AP: *Compend Cont Educ (Pract Vet)* 9:F418, 1987.

35.41.2 Clinical Signs

Experimentally and naturally poisoned horses show clinical signs by 2 to 3 weeks after continuous ingestion of locoweed.[1769,1771] The clinical signs include ataxia, conscious proprioceptive deficits, and depression, with alternating periods of frenzied or manic activity. There is sometimes a high-stepping, stringhalt-like gait.[1777] At rest the horses show intentional head tremor, flaccidity of the nose and lips, repetitive movements with the lips and tongue, and dysphagia.[1777] The clinical signs worsen when affected horses are handled or transported.

Signs in goats are similar, including ataxia, hypermetria, hyperesthesia, and muscle tremors.[1766] Forcing the head backward can result in falling, nystagmus, opisthotonos, seizures, and tetany.[1778] Tranquilization usually is ineffective for controlling the apparent hyperexcitability. Horses that survive locoweed poisoning retain an altered behavior. Abortions, stillbirths, and neonatal deaths can occur in all species exposed to these toxic plants, regardless of whether the dams have clinical signs of neurologic disease.[1764,1766–1768]

Neurologic signs in adult cattle include conscious proprioceptive deficits, hypermetria, weakness, depression, dull staring eyes, and loss of herding instinct. Heavy losses from abortions or malformed calves have also been described. The indolizidine alkaloids are secreted in the milk and may cause unthriftiness and weak suckling behavior in calves. Calves that have been exposed to the toxin in utero are weak and fail to thrive. Some may have flexural contractions of the limbs and lateral rotation of the carpus.[1779–1782] Ingestion of locoweed by certain cattle at high altitudes may result in the development of cor pulmonale.[1779,1780] Many cattle with mild signs of locoweed poisoning recover completely by 60 days after removal from the offending pastures. Ruminants with advanced chronic intoxication apparently have permanent loss of neural tissue.

Poisoned sheep have a star-gazing attitude and appear to be blind, nervous, and stiff. The normal flocking behavior is absent.[1765] Affected sheep may exhibit ptyalism. Testicular atrophy has been reported in rams.[1783] Affected animals have intercurrent pyogenic infections such as pneumonia, keratoconjunctivitis, and foot rot. This is thought to be related to the immunosuppressive effect of the plants on the T lymphocytes.[1784] Depression and reluctance to move induced by locoweed toxicity may predispose animals to other problems, such as water deprivation.[1785]

35.41.3 Clinical Pathology

1062

Microscopic examination of stained blood smears may reveal the presence of vacuolation in the cytoplasm of 1063
the lymphocytes. These changes are found in the majority of lysosomal storage disorders, but might be considered diagnostic of locoweed poisoning in animals with characteristic clinical signs and historical evidence of exposure. Serum concentrations of alkaline phosphatase (ALP) and aspartate transaminase (AST) may be helpful markers for toxicity; elevated concentrations were detected in sheep exposed to swainsonine in *Oxytropis sericea*.[1786] Definitive diagnosis can be established by assaying sera from affected animals for α-mannosidase and swainsonine.[1787]

35.41.4 Pathology

The microscopic abnormalities of the soft tissues of acutely poisoned animals are similar to those of the inherited lysosomal storage diseases of cattle, including cytoplasmic vacuolation of neurons, particularly Purkinje's cells, and cells in various other tissues.[1766,1777] Paraffin-embedded tissues can be examined using lectin histochemistry to characterize the stored material within the vacuoles.[1766,1788] Vacuolation of renal tubular epithelial cells may occur as early as 4 days after the start of daily feeding of 0.34 kg of locoweed to horses and may be present in animals exposed to toxic plants but clinically normal.[1766,1789] Pulmonary lesions associated with chronic ingestion of locoweed that may predispose to high-altitude disease (brisket disease) in cattle (see Chapter 31) include alveolar emphysema, bronchiolar constriction and hypertrophy, and interlobular edema and fibrosis. Pyloric or gastric ulcers have been reported in affected cattle.[1782,1789] Placental edema, fetal ascites, and hydrops allantois have been described in exposed pregnant cattle.

35.41.5 Treatment

There is no known effective long-term therapy for locoweed poisoning. Animals remain affected for a prolonged period after removal from the plants and may be permanently afflicted. Some recommend either tranylcypromine (60 mg PO), a monoamine oxidase inhibitor, and protryptyline (60 mg PO) or reserpine (3.125 g/500 kg IM once or 1.25 mg PO per animal once daily) for treatment of chronically affected animals.[1790] However, the efficacy of these treatments is unknown. Addition of a mineral supplement and a natural clay (clinoptilolite) to the diet of cattle ingesting locoweed did not prevent toxicity.[1791]

35.41.6 Prevention

Nonaddicted livestock normally do not eat locoweed if other forage is available. The intoxication may be prevented by supplemental feeding during the early spring and late summer. One report has described conditioning aversion to locoweed in horses using lithium chloride administered simultaneously with grazing of *Oxytropis sericea*.[1792] Whether this is a practical management tool in large numbers of animals has yet to be determined.

35.42 GRASS STAGGERS

Grass staggers is caused by a number of related products of plant or fungal metabolism. These compounds appear to have universal activity at the γ-aminobutyric acid (GABA) receptor of the internuncial neurons; therefore, intoxication causes clinical signs characteristic of released inhibition. The structural backbone of these toxins permits the molecules to bind to GABA receptors, thereby inactivating them. Some associated plant or fungal toxins also induce other physiologic effects, including agalactia, fever, and low productivity, because of a prolactin-like effect.

35.43 RYEGRASS STAGGERS

35.43.1 Perennial Ryegrass Staggers

Ingestion of toxic stands of perennial ryegrass *(Lolium perenne)* results in ataxia and tremors in horses, cattle, and sheep. The condition is recognized in livestock of New Zealand, Australia, Northern Europe, United States, South America, and Great Britain.[1793–1808] The case-attack rate may reach 100%, but the mortality rate is typically less than 50%.[1802] Conditions that favor toxicity include late seasonal growth, ambient temperatures over 23° C (73.4° F), and closely grazed pastures. For these reasons, the disease is seen exclusively between June and September in the Northern Hemisphere and between December and June in the Southern Hemisphere. The condition may appear 5 to 10 days after grazing on highly toxic pastures. For a pasture to develop toxicity, the ryegrass must constitute a majority of the forage growth.

Perennial ryegrass produces tremorgenic toxins when infested with the endophytic fungus *Acremonium loliae* or *Acremonium coenophialum*. The fungal infection confers resistance to the Argentine stem weevil, so there is a selective pressure for toxigenic cultivars. Strains of *Acremonium*-resistant ryegrass have been propagated but are difficult to maintain because of the devastating effects of the stem weevil infestation. The chemicals produced by *Acremonium*-infected plants are classified as indole terpenes. These compounds are chemically

related to the fungal tremorgens, penitrem A and fumotremogen. A number of separate toxic compounds have been isolated, including lolitrems A and B, paxilline, and peramine. Paxilline is a biosynthetic precursor of lolitrem B, which is related chemically to peramine. Peramine has the major antagonistic effects against the Argentine stem weevil. The lolitrems have the greatest tremorgenic effect on livestock.[1809] Concentrations of more than 2000 ppb of lolitrem B in forage or 1.68 mg/kg of forage have been associated with toxicity for sheep and cattle, respectively.[1810] The concentration of lolitrem varies seasonally in the same grass, and toxic pastures may become nontoxic over the course of the grazing season.[1811]

A relationship also exists between the frequency of poisonings and the proportion of plants infested by the *Acremonium* fungus. Infection rates below 25% are associated with sporadic cases, whereas plots containing 90% infection rates are associated with large outbreaks of staggers. Intoxication is most common on dry pastures where the perennial ryegrass is growing slowly under relatively low ambient temperatures. The *Acremonium* fungus can be identified by microscopic examination of boiled leaves. The fungus is in greatest prevalence in the summer and is found in the uppermost part of the leaf. To identify the fungus, the ryegrass leaves are immersed in a stain containing 0.06 g aniline blue in 50 mL of lactic acid in 250 mL of distilled water, 50 mL of glycerine, and 50 g of phenol. The mixture is boiled 5 minutes and mounted in lactophenol (20 g phenol, 16.7 mL lactic acid, 40 mL glycerine, and 20 mL water). For biologic assay of lolitrem, chloroform: methanol extracts of suspect plants are injected into mice. The recipients are then examined every few hours for tremors.

The endophyte-infested grasses also produce ergovaline or other ergopeptine alkaloids that exert prolactin-like activity. The resulting clinical signs are diarrhea, fever, tachypnea, and reduced weight gain.

High-peramine, low-lolitrem cultivars of *Lolium*[*] have been propagated. Such cultivars have partial protection against the stem weevil but do not cause staggers in pastured animals.[1812]

* Nui Endosafe, Dairying Research Corp., Hamilton, New Zealand.

1063

1064

35.43.2 Annual Ryegrass Staggers

Annual ryegrass toxicity is caused by corynetoxin, which is manufactured in the seed heads of annual ryegrass *(Lolium rigidium)* and related grasses. The seed head is infested by the nematode *Anguina agrostis (Anguina funesta)*. The parasitic infestation forms a gall that becomes secondarily infected by the bacterium *Clavibacter toxicus (Corynebacterium rathayii)*.[1813,1814] The *Corynebacterium* organisms produce corynetoxin; this neurotoxin has been purified using high-performance liquid chromatography (HPLC) and can be detected using an enzyme-linked immunosorbent assay (ELISA). The structure of corynetoxin is similar to that of the antibiotic tunicamycin.[1815] The corynetoxin is a glycolipid that inhibits the synthesis of lipid-linked oligosaccharides and blocks protein glycosylation.[1816,1817] Bacterial proliferation in the gall results in the formation of a yellow to orange exudate, which contains the toxin. The toxic material usually leaks out over the seed but occasionally remains encapsulated within the gall and cannot be detected by external examination. Galls that have a normal external appearance are toxic if the interior of the defect maintains a deep-orange color. Loss of color is associated with a decrease in the amount of toxicity. A method of evaluating toxic pastures based on enumeration of contaminated seed heads and ELISA to detect corynetoxin has been developed.

Outbreaks of staggers may occur in animals grazing the same pasture for months because the toxin is not inactivated by the rumen microflora, and daily doses may accumulate in sheep for as long as 9 weeks.[1818] Thus,

repeated exposure leads to an accumulation of the toxin and delayed onset of clinical disease. Also, the concentration of the toxin increases in the seed heads during the summer and is greatest as the plant dries and the seeds ripen.[1819,1820] Finally, toxic ryegrass may occur only in patches in the pastures, and the grazing patterns of the animals is altered by changes in the climatic conditions, the growth of the ryegrass, or introduction of new sheep. This could explain why outbreaks occur shortly after onset of inclement weather or after introduction of new sheep to the pastures.

Pathologic changes associated with annual ryegrass staggers include hemorrhage in the cerebellum, liver, and spleen. Ultrastructural changes include swelling of the capillary endothelial cells, dilation of the endoplasmic reticulum in the endothelial cells, mitochondrial degeneration, swelling of the astrocytic end feet, protein leakage across the blood-brain barrier, pyknosis and death of granular cell nuclei of the cerebellum, and changes in the neuropil adjacent to the damaged capillaries. These changes indicate that the toxin may access the central nervous system (CNS) by damaging the blood-brain–cerebrospinal fluid (CSF) barrier. CNS neurons could be affected because of vascular damage or direct activity of the toxins.[1821]

35.43.3 Clinical Signs and Pathologic Lesions

The clinical signs of annual and perennial ryegrass staggers are similar. For both disorders the case-attack rate usually is high, but mortality varies and can range from 0% to over 90%. The clinical signs may occur within 48 hours to several weeks after cattle are introduced to toxic pastures. The animals appear normal at rest but tremble when they are excited. The gait is stiff, and limbs are hypermetric. There are fine and coarse tremors of all major muscle groups, especially those of the shoulder and flank areas. The tremors worsen as the animal becomes excited. Other clinical signs include intentional head tremor, truncal sway, and base-wide stance. With continued stimulation, affected animals kneel and then fall over. While down, animals have stiff extension of the legs with occasional flailing and may display opisthotonos or convulsions. Frothy exudate from the mouth also has been described. After approximately 10 to 20 minutes of struggle, the animal recovers, stands, and walks back to the herd or flock. New cases and deaths can continue for as long as 1 week after the animals have been removed from the toxic pasture.

35.43.4 Differential Diagnosis

Grass staggers is easily recognized by clinical signs. The specific plant involved must be identified by examination of the pasture forage. Tremorgenic diseases of adult cattle are common throughout most of the world. In addition to ryegrass pastures, tremorgenic plants include *Swainsona luteola* and *Swainsona galegifola; Solanum dimidiatum* and *Solanum fastigiatum; Astragalus* species; red buckeye; *Phalaris* species (canary and reed canary grass); *Eupatorium rugosum* (white snakeroot); *Cynodon dactylon* (Bermuda grass); Dallis grass infested with the fungus *Claviceps paspali; Polypogon monospeliensis* (annual beard grass); *Pennisetum clandestinum* (kikuyu grass); and the mycotoxins of *Penicillium cyclopium*.[1820] Hypomagnesemia has been reported to cause cerebellar degeneration under some circumstances. The storage diseases (α- and β-mannosidosis, generalized glycogenosis, globoid cell leukodystrophy, neuronal lipodystrophy) may also be important differential diagnoses for ataxic animals with tremor and cerebellar signs.

35.43.5 Treatment

There is no specific treatment for grass staggers. If the animals are removed from toxic pastures as soon as signs are first seen, the mortality rate is low despite the high number of affected animals. Several months may

elapse before the neurologic signs resolve completely. Treatment with high doses of magnesium chloride has been recommended, although others have shown it to be ineffective for controlling the muscular spasms.[1822] Pastures may lose toxicity after rain and growth of new grass. In subtropical regions, cattle should not be introduced to toxic pastures until the late fall or winter, when less toxic growth becomes abundant.

35.43.6 Prevention

Ammoniation of dried feed has been recommended as a method of reducing the toxicity of hay. This treatment simultaneously increases the digestibility and protein equivalency of the forage.[1823] For preventing annual ryegrass staggers, high-risk pastures can be identified by visually examining seed heads for infected galls. ELISA is sufficiently sensitive to identify one infected seed gall per 100 g of dried seed heads and also can accurately predict toxicity in pastures.[1824] The most practical strategy for controlling annual ryegrass toxicity is to break the nematode's life cycle by killing the ryegrass for two or three growing seasons. Otherwise, pastures remain perpetually toxic. Integrated control measures that have been recommended for prevention of annual ryegrass toxicity include applying herbicides in the spring, seeding the pastures with legumes, burning the infected pasture grasses during early autumn, and applying ryegrass-selective herbicides in the summer months, combined with heavy winter grazing.[1825]

Prevention of perennial ryegrass staggers using endophyte-free cultivars has been recommended. Such resistant biotypes of ryegrass lack resistance to the Argentine stem weevil and consequently are less productive than other biotypes. The most convenient solution has been to minimize exposure of the animals until fall rains stimulate less toxic pasture growth. Newer cultivars containing fewer tremorgens may be useful in the future.

1064

1065

35.44 BERMUDA GRASS STAGGERS

Bermuda grass *(Cynodon dactylon)* occasionally may become toxic for livestock.[1228] Cattle are most susceptible, followed by sheep, goats, and horses. Although the nature of the toxic principle in Bermuda grass is unknown, several factors, including sooty mold (*Pullularia* species), endogenous basic alkaloids, and leaf hopper infestation, have been associated with toxic pastures.[1826]

Animals may develop clinical signs as early as 36 hours after consuming toxic forage. Experimentally poisoned goats have developed clinical signs 8 days after being fed 772 g/head/day of toxic hay.[1826] The toxin survives drying. Hay that is cut from offending pastures may remain toxic for as long as 9 years.[1827] The pharmacologic nature of the toxin is unknown; however, the sclerotia of *Claviceps purpurea* have been identified on the seed heads of toxic pastures.[1828] Pastures that are toxic remain so for successive seasons unless the vegetation is burned off and the ground is tilled and reseeded.

The clinical signs of Bermuda grass intoxication occur suddenly, usually simultaneously, in several animals in the herd. In some cases, most of the animals on a single pasture may be affected, whereas animals on an adjacent pasture remain normal. The clinical disease is indistinguishable from ryegrass staggers (see preceding sections). The electroencephalograms of affected animals are normal, indicating that the biochemical lesion is below the cortical level.[1829] The mortality rate is low, and deaths usually occur from self-inflicted trauma. Affected animals recover 2 days to 2 months after removal from the pasture. Tremors may be controlled using intravenous diazepam (0.1 to 1.0 mg/kg two or three times daily as needed).

35.45 KIKUYU GRASS POISONING

A nervous system disease characterized by depression, ataxia, drooling of saliva, and ruminal distention occurs in cattle and sheep of northern New Zealand that are grazing kikuyu grass *(Pennisetum clandestinum)*.[1830]

35.46 DALLIS GRASS STAGGERS (*PASPALUM* STAGGERS; *CLAVICEPS PASPALI* TOXICITY; NERVOUS ERGOTISM)

Ingestion of Dallis grass infected with the ergot fungus *Claviceps paspali* produces a tremorgenic disease similar to that of Bermuda and ryegrass staggers. Other *Paspalum*-type grasses that may become toxic include Argentine bahia grass *(Paspalum dilatatum)* and water couch grass *(Paspalum distichum)*. Horses are susceptible to the toxin, but the condition occurs most often in cattle. The disease has been recognized in the United States, Great Britain, Australia, and New Zealand.[1831–1835]

Claviceps paspali first attacks the pistil of the grass flower and replaces the ovary with fungal tissue. The fungus secretes a sticky fluid, the "honeydew," which contains a large number of spores but little toxin. The fluid hardens into a mature sclerotia containing large amounts of toxin. Toxic stands of Dallis grass can be recognized by the presence of numerous small, reddish brown or black sclerotia measuring 3 to 5 mm in diameter on the seed head of the plant. The fungus produces a number of neurologically active agents. Some of the products resemble lysergic acid diethylamine (LSD) in structure and activity, whereas others may act as dopaminergic agonists. Animals apparently develop a craving for the infested seed heads and graze them selectively. The toxin remains active in cured hay. Toxin production is greatest when there is a wet period after formation of the seed heads. Mowing the toxic pastures and removing or burning the infested seed heads are effective for preventing further outbreaks of the disease. If the amount of rainfall diminishes after mowing, the new growth usually is nontoxic.

The clinical signs of Dallis grass staggers are similar to those described earlier for ryegrass, including coarse and fine muscular fasciculations, head tremors, spastic hypermetric gait, and falling. The clinical signs are exacerbated by fright or external stimulation. Clinical diagnosis is made by visible detection of the toxic agent in the feed or by using thin-layer chromatography (TLC). Animals recover spontaneously within 1 to 3 months after being removed from the pasture.

35.47 CANARY GRASS STAGGERS (*PHALARIS* STAGGERS)

Cattle or sheep that graze on certain *Phalaris* species of canary grass *(P. arundinacea, P. tuberosa, P. acquatica, P. angusta, P. caroliniana, P. brachystachys)* grown under specific environmental conditions may develop neurointoxication.[1836–1841] *Phalaris* poisoning has been reported in Australia, New Zealand, South Africa, Norway,[1842] South America,[1843] and the United States,[1844] where the plant can be found in Virginia, Colorado, Oregon, Florida, Texas, Georgia, Mississippi, Alabama, and California.[1845] The case-attack rate may reach 80%,[1839] and the mortality rate ranges from 4% to 40%.[1837,1839] Acute deaths may occur as early as 4 to 12 hours after commencement of grazing on a toxic pasture.[1837,1840] Animals usually recover by 8 days after removal from offending pastures, but signs can persist for as long as 1 month after removal, and relapses can occur for up to 5 months.[1836,1837,1840]

Continuous exposure to low concentrations of alkaloid (<0.001% of dry matter intake) over 40 days has resulted in severe toxicosis in sheep on a drylot.[1846]

The toxic principles of canary grass are tryptamine alkaloids (dimethylated indolealkyl amines), which are found in one or more *Phalaris* species *(P. tuberosa, P. minor,* and *P. arundinacea*).[1839] The most potent of the toxins is the alkylamine 5-methoxydimethyltryptamine. Intravenous doses of this compound as low as 0.1 mg/kg can cause severe neurologic signs in sheep in 16 seconds.[1841] The toxins competitively inhibit the initial step in the breakdown of serotonin by monoamine oxidase and act on midbrain and medullary nuclei via presynaptic serotonin type 1 cholinergic receptor sites. The overall activity of the toxin is to enhance response to excitatory inputs.[1847]

The dynamics of toxin production have been examined.[1848] The concentration of alkaloid in the plant is increased by a reduction of light intensity (shade) but not by a decrease in length of the daylight.[1848] If light intensities are high, the grass is unlikely to be toxic unless soil nitrate levels are also high.[1848] Rapid growth of the grass also favors the formation and accumulation of toxin. Other factors that enhance the toxicity of a pasture include fog, humidity, or rain, followed by sunny, warm weather or sunshine on nitrogen-fertilized pastures.[1848] Although there is no specific age-related susceptibility to the toxin, only weaned animals tend to be affected during an outbreak. Many outbreaks occur when hungry sheep ingest large amounts of toxic grass over a short period.[1837] The disease has also occurred 3 to 5 days after a rainfall has ended a period of drought.[1843]

Electromyographic studies have indicated that the tremors and spasms probably originate from the spinal cord and the peripheral nervous system. Excitation leads to increased muscle tone and extensor rigidity.[1849]

There are at least two distinct clinical forms of the intoxication: acute death from cardiovascular collapse and a more chronic nervous form.[1838] The cardiovascular form of the disease occurs by 12 to 72 hours after animals are placed on a toxic pasture.[1838,1840] Affected animals die suddenly from heart failure while being herded off toxic pastures. Animals also may be found dead with the head fixed in opisthotonos and the legs in rigid extension. The ground surrounding the limbs is disturbed, indicating that the animal died in convulsions. Signs associated with cardiac collapse include acute dyspnea, cyanosis, pounding heart sounds, irregular heart rate with alternating periods of extreme tachycardia (170 to 240 beats/min), and then bradycardia.[1841,1846]

1065
1066

The nervous form of the disease is more prolonged and occurs after repeated exposures of 2 to 33 weeks' duration. Signs may be delayed for as long as 4 months after removal from the toxic grass.[1844] The clinical signs include hyperexcitability, exaggerated responses to auditory or tactile stimuli, fine muscular fasciculations (particularly of masseter muscles), licking of the lips, wrinkling of the facial muscles, repetitive chewing, inability to swallow, flaring of the nostrils, ptyalism, nystagmus, intentional head tremor, ear and tail twitching, base-wide stance, reduced menace response, and deficient pupillary reflexes.[1841,1849] The gait of affected sheep is described as stiff legged, with both hindlimbs moving in unison (“rabbit hopping”). Affected sheep buckle at the knees and assume sternal recumbency with the hindquarters elevated. They then fall into lateral recumbency and flail wildly while attempting to stand.[1838] Poisoned cattle also show incoordination and repeated stabbing movements with the tongue and are unable to grasp the forage. They salivate profusely and drop feed from the mouth. Eventually the animals die of starvation. There may be an increased protein concentration (40 to 100 mg/mL) and white blood cell count (4 to 50 mononuclear cells/dL) in CSF of affected animals.[1836] Animals may survive the initial signs but have neurologic symptoms for as long as 10 months.[1850]

For confirmation of a diagnosis, the amount of tryptamine alkaloids in suspect grasses can be measured. Alkaloid concentrations greater than 30 to 50 mg/100 g dry weight of forage are considered toxic for sheep.[1848,1849]

The pathologic lesions in the CNS of affected animals include focal, demarcated, greenish or slate-gray discoloration in the pons, medulla, and corticomedullary junction of the kidney; intracytoplasmic accumulations of greenish brown pigment in the dorsal root ganglia and medullary nuclei; neuronal loss; focal gliosis; and swelling of the axonal sheaths in the ventromedial aspect of the spinal cord.[1836,1839] The pigment is thought to originate from metabolism and deamination of the toxic alkylamines but is not thought to play a direct role in the development of the neurologic deficits.[1845,1849] Other lesions in cattle that have died acutely include ulcerative abomasitis, jejunitis, and ileitis; subcapsular renal hemorrhage; and ecchymoses of the pericardium and epicardium.

Administration of cobalt to animals on toxic grass pastures is protective. The biochemical function of cobalt is thought to be related to increased ruminal inactivation of the toxins. Weekly administration of 28 mg of cobalt to each animal is recommended to prevent clinical signs in exposed sheep.[1844,1845,1850–1852] This dosage is much higher than that delivered by standard supplementation. Additional recommendations include removal of affected animals from the offending pasture, sedation with a phenothiazine tranquilizer, and administration of sodium pentobarbital or diazepam to convulsive sheep. *Phalaris* plants may also contain potentially toxic concentrations of nitrate or cyanide. In any outbreak of suspected *Phalaris* toxicosis with acute signs of sudden death, cyanide and nitrate poisonings should also be considered.[1853]

To prevent *Phalaris* poisoning, animals should be removed from the toxic grasses. The concentration of dimethylindolealkyl amines may be reduced by curing the forage as hay. Ensiling the canary grass does not reduce the amount of toxins.[1854]

35.48 *PENICILLIUM CYCLOPIUM* (TREMORGEN) INTOXICATION

Ruminants that ingest toxic species of *Penicillium* develop clinical signs that are indistinguishable from those of Dallis, ryegrass, *Phalaris,* and Bermuda grass staggers.[1855–1858] The tremors are caused by mycotoxins,[1858] which can be classified into four major groups: the aflatrem-paxilline group, verruculogen-fumotremogen group, territrem group, and tryptoquivaline group. Of these, the most important fungal tremorgens are aflatrem, penitrem A, fumotremogen B, and verruculogen. Verruculogen and fumotremogen B can be isolated from cultures of *Penicillium estinogenum*. Penitrem A is elaborated from *Penicillium nigricans, Penicillium anitellum, Penicillium cyclopium, Penicillium clavigerum,* and *Aspergillus canescens*. Verriculogen has also been identified in pure cultures of *Aspergillus fumigatus*.[1859,1860]

Ingestion of moldy cornstalks constitutes the most common source of fungal tremors in livestock. The fungi proliferate in the corn but do not produce tremorgens until the stalks touch the ground. After production at or near the soil surface, the toxins translocate in plants through root absorption.[1858]

The pathophysiologic mechanisms by which mycotoxins affect the CNS are unknown, but there is increased release of the transmitter amino acids aspartate, glutamate, and γ-aminobutyric acid in the corpus striatum, indicating the presence of a reversible biochemical lesion.

Diagnosis is based on the clinical signs, demonstration of the mycotoxin in the feed, and identification of the fungal elements in the feces. There is no specific treatment for the intoxication. Affected animals recover

completely when they are removed from infected pastures. The diagnosis of tremorgenic fungal intoxication is difficult. The mycelial elements survive degradative conditions in the gastrointestinal tract and can be isolated from the feces of intoxicated animals. Penitrem A and verriculogen can be demonstrated in the forage by TLC or mouse assay.

35.49 TREMORGENIC NEUROTOXICOSIS FROM *ASPERGILLUS CLAVATUS*

Ingestion by cattle and sheep of fodder contaminated by the fungus *Aspergillus clavatus* can result in ataxia, weakness, and tremors, similar to signs caused by ingestion of other neurotoxic molds.[1861,1862] Clinical signs include ataxia, knuckling, muscle weakness and tremors that may be exacerbated by handling, hypersalivation and drooling, altered behavior, loss of appetite, reduced milk production, muscle spasms, recumbency, opisthotonos, and death. Cases have occurred worldwide, linked to feeding sprouted grains and the by-products of beer production, both of which provide an environment for growth of the mold. Factors that can encourage mold growth include high ambient temperature and high humidity.[1861] Hematologic changes include evidence of dehydration, moderate neutrophilia, hypochromasia, and microcytic erythrocytes. Changes in clinical chemistry include elevated creatine kinase (possibly from recumbency), AST, γ-glutamyltransferase, and glutamate dehydrogenase activity. The toxicity of *A. clavatus* is attributed to a variety of tremorgenic neuromycotoxins, including patulin, tryptoquivaline, tryptoquivalone, nortryptoquivalone, cythochalasin E, cythochalasin K, escladiol, and clavatol.[1862]

35.50 DISEASES PRODUCING SPINAL CORD OR PERIPHERAL NERVE SIGNS

35.50.1 CERVICAL VERTEBRAL STENOTIC MYELOPATHY (WOBBLER SYNDROME; CERVICAL STENOTIC MYELOPATHY; CERVICAL VERTEBRAL INSTABILITY)

BONNIE R. RUSH

35.50.2 Clinical Signs

Cervical vertebral stenotic myelopathy (CVSM) is a common cause of symmetric spinal ataxia in horses. Neurologic gait deficits are caused by spinal cord compression by stenotic and malformed cervical vertebrae.[1863] A neurologic examination is performed to assess the symmetry of deficits and the severity of weakness, ataxia, and spasticity.[1864] Gait analysis is performed at the walk; neurologic deficits can be accentuated by circling, elevation of the head, and maneuvering over obstacles and inclines. Ataxia or proprioceptive loss is manifested by circumduction of the hindlimbs, posting (pivoting on the inside hindlimb during circling), and truncal sway. In most cases, pelvic limb ataxia is more pronounced than forelimb deficits. Moderately to severely affected horses have lacerations on the heel bulbs (wobbler heels) and medial aspect of the forelimbs from overreaching and interference. Stumbling and toe dragging indicate weakness. The hooves of horses with prolonged clinical signs of CVSM are chipped, worn, or squared at the toe. At rest, affected horses may have a base-wide stance and may demonstrate delayed responses to proprioceptive positioning. When prompted to back, horses may stand base wide, lean backward, drag their hindlimbs, and step on their hindfoot with a forelimb. The musculature of the neck may appear disproportionately thin compared to the rest of the body, and in some horses, prominent articular processes of the fifth and sixth cervical vertebrae may be evident.[1865]

Occasionally, weakness and stumbling are more pronounced in the forelimbs. This is usually observed in horses with stenosis of the caudal cervical vertebrae (C6-C7) caused by compression of the cervical intumescence. Alternatively, arthropathy of the caudal cervical vertebrae may produce cervical pain and forelimb lameness from peripheral nerve compression, without producing clinical signs of spinal cord compression.[1866] Affected horses typically travel with a short cranial phase of the stride and a low foot arc of the forelimbs and may stand or travel with their head and neck extended. Rarely, diskospondylosis of the cervical vertebrae will produce a short-strided gait and cervical pain, with or without spinal ataxia. Horses with diskospondylosis or arthropathy of the caudal vertebrae may demonstrate increased rate and depth of respiration with cervical manipulation because of pain.

The condition has been reported in most light and draft breeds.[1867] Thoroughbreds are particularly predisposed to CVSM, which affects approximately 2% of the population. Between 10% and 50% of thoroughbreds have characteristic developmental malformations of the cervical vertebrae without spinal cord compression.[1868,1869] Male horses are more frequently affected than females. Most horses with CVSM are 6 months to 3 years of age at presentation. Nonetheless, age (≥4 years) does not preclude a diagnosis of CVSM; spinal cord compression caused by vertebral abnormalities is routinely diagnosed in adult horses, including geriatric horses.

The onset of neurologic gait deficits is typically insidious, with progression of ataxia for several weeks, followed by stabilization (plateau) of clinical signs.[1867,1870] Owners may report a traumatic incident with the onset of clinical signs of CVSM. The event may be the result of mild neurologic deficits, with the injury exacerbating the clinical signs of spinal cord compression. Asymmetric ataxia and paresis may be occasionally observed in horses with dorsolateral compression of the spinal cord by proliferative, degenerative articular processes and periarticular soft tissue structures.

35.50.3 Pathophysiology

CVSM appears to be a manifestation of developmental orthopedic disease. Developmental disease of the appendicular skeleton, such as physitis, joint effusion, osteochondrosis, and flexural limb deformities, occurs more often in young horses with CVSM.[1871] A direct cause-and-effect relationship between osteochondrosis and CVSM has not been identified; however, the association between the frequency of occurrence of osteochondrosis and CVSM indicates that the two conditions have a similar pathophysiology.

The etiology of osteochondrosis and CVSM appears multifactorial, consisting of genetic and environmental influences. It is unlikely that CVSM is heritable by simple mendelian dominant recessive patterns.[1872] The mode of inheritance more likely involves multiple alleles and variable penetrance, which determine genetic predisposition to CVSM. A high plane of nutrition, micronutrient imbalance, rapid growth, trauma, and abnormal biomechanical forces probably contribute to the development of CVSM in genetically predisposed animals.

Dietary copper, zinc, and carbohydrates are thought to play a role in the pathogenesis of osteochondrosis and CVSM. Low dietary copper (12 ppm) and high dietary zinc (1000 to 2000 mg/kg of dry weight) concentrations cause osteochondrosis in foals, whereas copper supplementation (55 ppm) reduces the incidence of osteochondrosis of the axial and appendicular skeleton.[1873,1874] Copper supplementation does not eliminate developmental orthopedic disease, suggesting the existence of other etiologic factors. Excessive carbohydrate in the diet is hypothesized to contribute to the pathogenesis of osteochondrosis through endocrine imbalance.[1875,1876]

Spinal cord compression can be dynamic or static in horses with CVSM.[1870,1877] *Dynamic compression* occurs because of vertebral instability and causes intermittent spinal cord compression during ventroflexion of the neck; compression is relieved when the neck is in the neutral position. Pathologic changes most often observed in horses with dynamic compression are instability between adjacent vertebrae, malformation of the caudal vertebral epiphysis (caudal epiphyseal flare), and malformation or malarticulation of the articular processes. Osteochondrosis of the articular processes is not always present at the site of spinal cord compression in horses with dynamic compression.[1870] The intervertebral sites most frequently affected by dynamic compression are C3-C4 and C4-C5.

Static compression is defined as continuous spinal cord impingement regardless of cervical position. It occurs predominantly in the caudal cervical region, C5-C6 and C6-C7. Static compression is exacerbated by thickening of the dorsal lamina, hypertrophy of the ligamentum flavum, and degenerative joint disease (DJD) of the articular processes. Both static and dynamic compression are associated with narrowing of the vertebral canal from C3-C6, regardless of the site of spinal cord compression, indicating that generalized vertebral canal stenosis is an important factor in the pathophysiology of CVSM.[1878]

Histopathologic examination of the spinal cord identifies myelin degeneration (ventral and lateral funiculi), malacia, focal neuronal loss, and fibrosis at the sites of compression. Wallerian degeneration occurs in ascending white matter tracts cranial to the affected site and in descending tracts distal to the site of spinal cord compression.[1879]

1067

1068

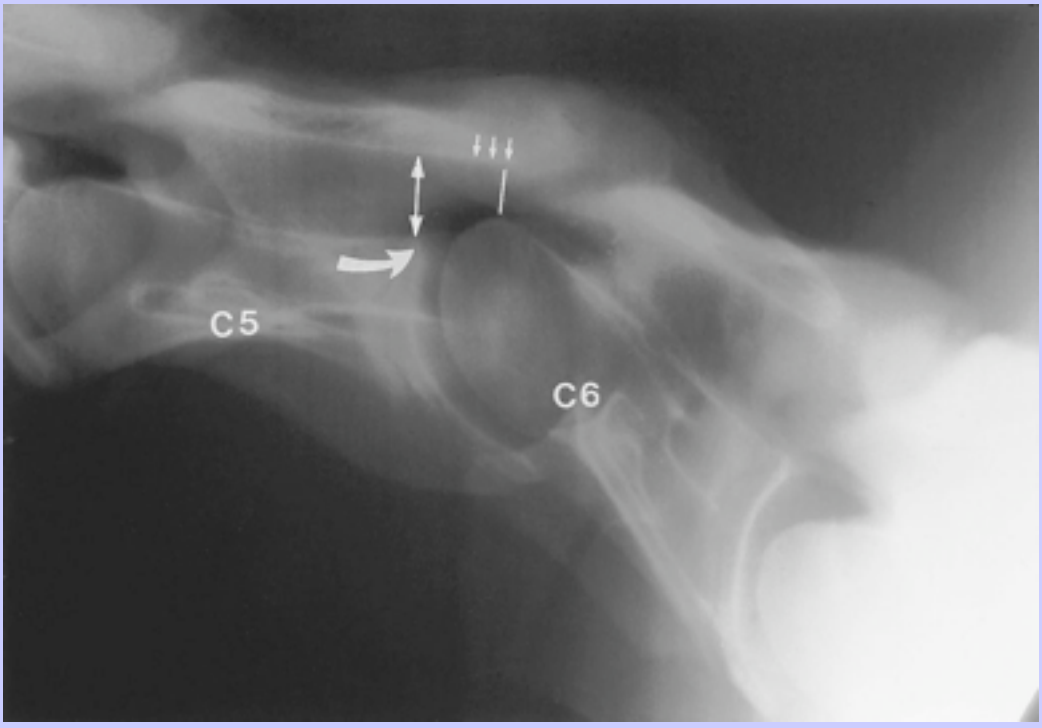
35.50.4 Diagnosis

Radiographic examination and cerebrospinal fluid (CSF) analysis are indicated in horses with symmetric tetraparesis and ataxia to differentiate CVSM from other spinal cord disorders. The most important differential diagnoses for horses with symmetric tetraparesis and ataxia include equine herpesvirus myeloencephalitis, equine protozoal myeloencephalitis, equine degenerative myeloencephalopathy, and spinal cord/vertebral trauma. Cytologic CSF findings usually are unremarkable in horses with CVSM. When CSF findings are abnormal, the alterations are consistent with acute spinal cord compression, such as mild xanthochromia and mild increases in protein concentration.

Survey radiographs of the cervical spine are obtained in standing, sedated horses. Cervical radiographs are evaluated by subjective assessment of vertebral malformation and objective determination of vertebral canal diameter.[1878] The five categories of cervical malformation subjectively assessed in horses with CVSM are DJD of the articular processes, subluxation between adjacent vertebrae, flare of the caudal physis of the vertebral body, abnormal ossification patterns, and caudal extension of the dorsal laminae[1878,1880] (Figs. 35-26 and 35-27). Although the presence of characteristic vertebral malformations supports the diagnosis of CVSM, subjective evaluation of survey radiographs does not reliably discriminate between horses affected and those unaffected by CVSM.[1868,1878] DJD of the articular processes of the caudal cervical vertebrae is the most common and severe malformation observed in affected horses.[1878] However, degenerative arthropathy occurs in 10% to 50% of nonataxic horses and is the most common and severe vertebral malformation in horses without CVSM.[1869,1878] Subjective evaluation of degenerative arthropathy of the articular processes may lead to a false-positive diagnosis of CVSM.[1868]

The vertebral canal diameter is objectively assessed by determining the sagittal ratio.[1876] The *sagittal ratio* is obtained by dividing the minimum sagittal diameter of the vertebral canal by the width of the corresponding vertebral body. The minimum sagittal diameter is measured from the dorsal aspect of the vertebral body to the ventral border of the dorsal laminae, and the vertebral body width is measured perpendicular to the vertebral canal at the widest point of the cranial aspect of the vertebral body (Fig. 35-28). The sagittal ratio eliminates error caused by magnification because the vertebral canal and vertebral body are in the same anatomic plane. The sagittal ratio should exceed 52% from C4 through C6 and 56% at C7 in horses weighing more than 320 kg. The sensitivity and specificity of the sagittal ratio for identification of CVSM-affected horses are approximately 89% for vertebral sites C4 through C7.[1881] Accurate measurement of the sagittal ratio requires a precise, lateral radiograph of the cervical vertebrae. Oblique views yield indistinct margins of the ventral aspect of the vertebral canal, resulting in erroneous values for minimum sagittal diameter and vertebral body width. *Intervertebral ratios* have been suggested to improve the ability to identify the site of spinal cord compression.[1882] This measurement is obtained by determination of the minimum distance from the craniodorsal aspect of the vertebral body to the caudal aspect of the vertebral arch of the immediately rostral vertebra. This value is divided by the width of the vertebral body. Reference values for this technique have not been published.

Fig. 35-26 Survey radiograph of fifth *(C5)* and sixth *(C6)* cervical vertebrae. Bony malformations include flare of the caudal physis (*curved arrow,* C5), caudal extension of the dorsal lamina (*small arrows,* C5), and subluxation and malalignment of the C5-C6 articulation. *Solid line,* Intervertebral canal diameter of C5-C6 articulation; *double-headed arrow,* intravertebral canal diameter of C5.



The semiquantitative scoring system developed by Mayhew et al.[1880] should be used in foals under 1 year of age to assess cervical radiographs for diagnosis of CVSM. The scoring system combines objective measurement of the vertebral canal diameter and subjective evaluation of vertebral malformation. Stenosis of the vertebral canal is assessed by determining the intervertebral and intravertebral minimum sagittal diameters. These values are corrected for radiographic magnification by dividing them by the length of the vertebral body (see Fig. 35-26). Foals that measure below the mean are assessed 5 points, and foals that measure 2 standard deviations (SD) below the mean or fall below the mean at multiple sites are assessed 6 to 10 points (Table 35-15). Cervical vertebral malformation is determined by subjective assessment of five categories: encroachment of the caudal epiphysis of the vertebral body dorsally into the vertebral canal; caudal extension of the dorsal lamina to the cranial physis of the next vertebra; angulation between adjacent vertebral bodies; abnormal ossification of the physis; and DJD of the articular processes. The maximum score allotted for each category of bony malformation is 5 points. A total score of 12 or higher (maximum, 25) confirms the radiographic diagnosis of CVSM. Stenosis of the vertebral canal and malalignment between adjacent vertebrae are the most discriminating parameters in this semiquantitative scoring system to differentiate CVSM-affected foals from normal foals.

1068 1069

Fig. 35-27 Survey radiograph of fifth and sixth cervical vertebrae. Degenerative joint disease, bony proliferation, and a facet fracture *(arrows)* can be seen on the articular processes of the C5-C6 articulation.

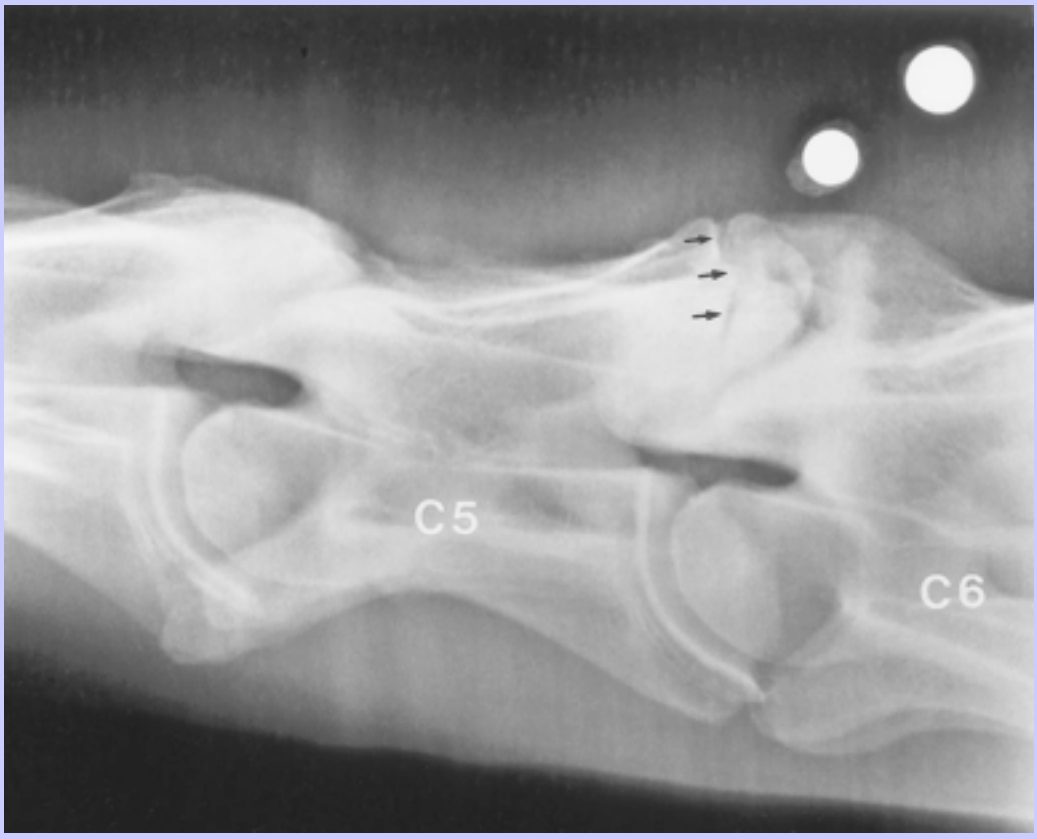


Fig. 35-28 Survey radiograph of fourth and fifth cervical vertebrae. The sagittal ratio is determined by dividing the minimum sagittal diameter *(double-headed arrows)* by the width of the corresponding vertebral body *(lines)*.

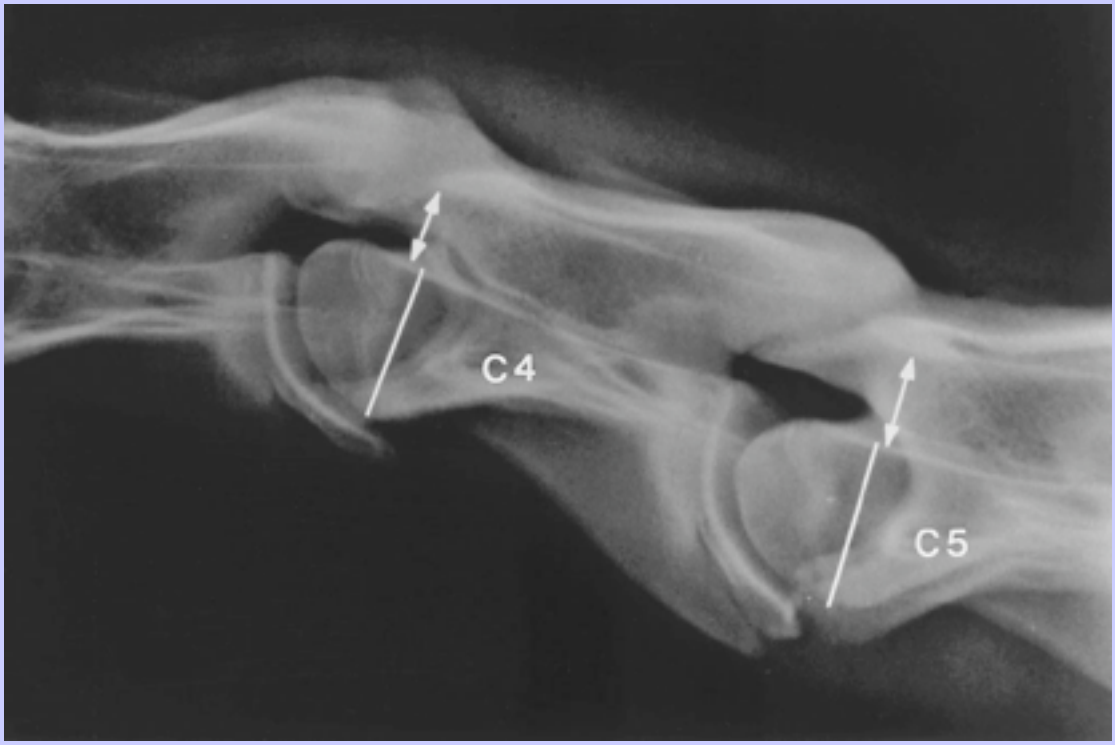

Survey radiographic examination of the cervical vertebrae determines the likelihood of spinal cord compression. Myelographic examination is required for definitive diagnosis of CVSM, identification of the location of affected vertebral sites, and classification of compressive lesions. The clinician should use radiographic interpretation to classify the patient into one of the following categories:

1 Low sagittal ratio (<48% at C4 to C6), moderate to severe bony malformation; myelographic examination to identify sites of spinal cord compression and to classify lesions as static or dynamic.

2 Marginal sagittal ratio (48% to 56%), mild to moderate bony malformation; myelographic examination to confirm or rule out CVSM.

3 High sagittal ratio (>56%), minimal bony malformation; other differential diagnoses pursued.

Table 35-15 Mean Minimum Sagittal Diameters* and Corrected Minimum Sagittal Diameters of Cervical Vertebrae in Foals without Neurologic Disease

Cervical Vertebral Site	Minimum Sagittal Diameter (mm) ± SD	Corrected Minimum Sagittal Diameter (%) ± SD
C2	23 ± 1	18 ± 1
C2-C3	28 ± 4	33 ± 2
C3	20 ± 1	24 ± 2
C3-C4	25 ± 2	30 ± 2
C4	20 ± 1	24 ± 2
C4-C5	25 ± 2	31 ± 2
C5	21 ± 1	25 ± 2
C5-C6	26 ± 3	34 ± 3
C6	21 ± 1	27 ± 2
C6-C7	31 ± 5	46 ± 5
C7	23 ± 1	35 ± 2

SD, Standard deviation.

From Mayhew IG et al: Diagnosis and prediction of cervical vertebral malformation in thoroughbred foals based on semi-quantitative radiographic indicators, *Equine Vet J* 25:435, 1993.

Myelographic examination is performed under general anesthesia with the patient in lateral recumbency.[1883] The landmarks for cisternal puncture at the atlantooccipital site are the cranial border of the wings of the atlas, the caudal border of the occipital protuberance, and the dorsal midline. The poll region is aseptically prepared and the head flexed at a 90-degree angle to the cervical vertebral column. The spinal needle (3½-inch, 18-gauge needle with stylet) is introduced and directed toward the lower jaw. The needle is advanced until the dura mater is penetrated, which often produces a "popping" sensation. Clear CSF should drip rapidly or flow from the hub with successful placement of the needle. An equal volume (20 to 40 mL) of CSF is removed before injection of a contrast agent. From 20 to 40 mL of contrast medium produces sufficient positive-contrast opacity to identify spinal cord compression in adult horses.[1883] The bevel of the spinal needle is directed caudally, and contrast medium is injected at a constant rate over 5 minutes. The head and neck are elevated under a wedged platform for 5 minutes at 30 to 45 degrees to facilitate caudal flow of the contrast medium. Iohexol (350 mg iodine/mL) and iopamidol (370 mg iodine/mL) are the most popular nonionic, water-soluble contrast media used for equine myelographic studies.[1884–1886] These second-generation agents cause less neurotoxicity and meningeal irritation than metrizamide.[1887]

It is difficult for investigators to agree on myelographic criteria for definitive diagnosis of CVSM. In many cases the site of compression (or lack thereof) is obvious, and all recommended criteria would produce the same result. However, there is a population of horses for which myelographic interpretation is more difficult. Many reports recommend a 50% or greater decrease in the sagittal diameter of the dorsal contrast column, paired with

obliteration of the ventral contrast column.[1883] The decrease in the sagittal diameter of the contrast column is determined by comparing the value at the intervertebral space to a midvertebral site cranial or caudal to the suspected intervertebral space. The 50% reduction should be interpreted conservatively, given the propensity for false-positive diagnosis; a 70% reduction may be more reliable.[1882] Some investigators prefer to use a diagnostic criterion of less than 2 mm of dorsal contrast column (or smaller) to reduce false-positive results on myelographic studies, but this criterion will increase the risk of false-negative diagnosis. Most recently, a 20% reduction in dural diameter (height of dural sac) at a given intervertebral junction, compared with the dural diameter at the level of the midvertebral body, has been suggested as the most reliable indication of spinal cord compression.[1882]

A complete myelographic examination should include neutral and stressed (flexed and extended) views of the cervical vertebrae.[1863,1883] Horses with dynamic spinal cord compression show obliteration of the dorsal and ventral contrast columns during ventroflexion of the neck (Fig. 35-29), whereas spinal cord compression is not apparent with the neck in the neutral position. Static vertebral canal stenosis is characterized by constant spinal cord compression regardless of cervical position (Fig. 35-30). In some cases of static compression, ventroflexion of the neck stretches the ligamentum flavum and relieves spinal cord compression, whereas hyperextension exacerbates compression. In horses with obvious sites of spinal cord compression on neutral myelographic views, excessive flexion and extension of the neck should be avoided while obtaining dynamic views to prevent exacerbation of spinal cord injury.

1070 1071

Fig. 35-29 Myelographic examination of C3 through C6 with the cervical spine in ventroflexion. Dynamic instability and spinal cord compression are present at the C3-C4 and C5-C6 articulations. The ventral contrast columns are obliterated, and the dorsal contrast columns are narrowed (to less than 2 mm) at C3-C4 and C5-C6 *(arrows)*.

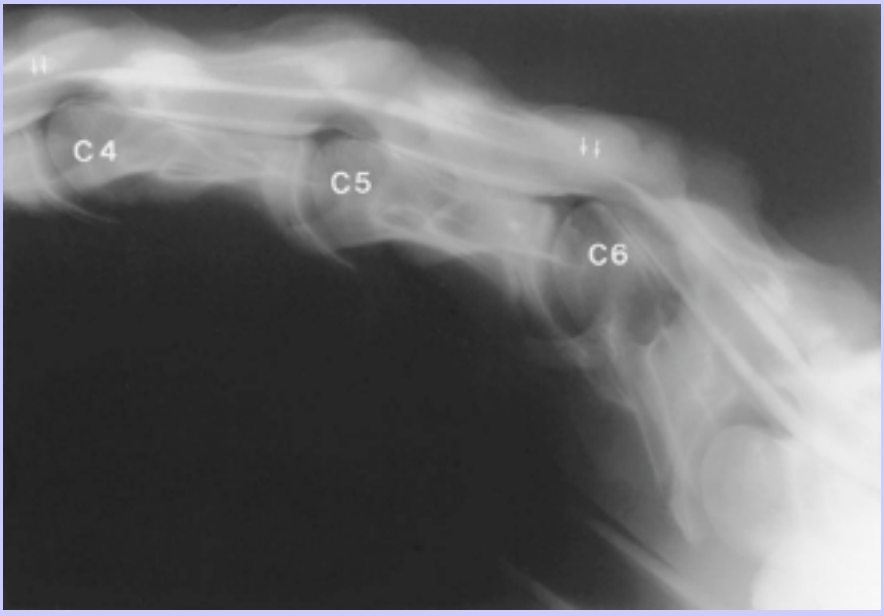

Fig. 35-30 Myelographic examination of C5 through C7 with the cervical spine in neutral position. Static spinal cord compression is demonstrated by obliteration or narrowing (to less than 2 mm) of the dorsal and ventral contrast columns at C5-C6 and C6-C7 *(arrows)*.

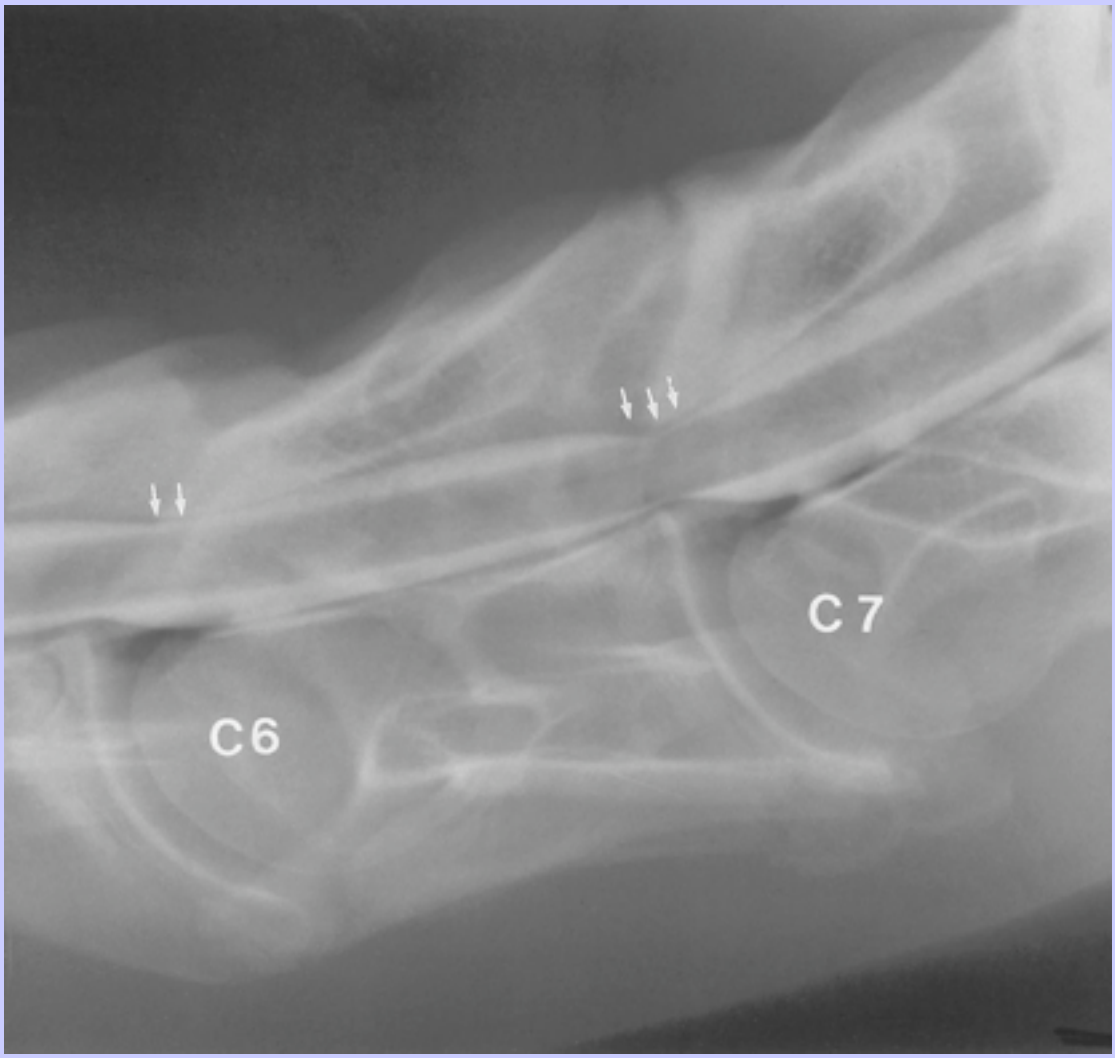


Horses should be monitored for 24 hours after the myelographic procedure for depression, fever, seizure, and worsening of neurologic status.[1888] Worsening of neurologic status after myelography may result from spinal cord trauma during hyperflexion, iatrogenic puncture of the spinal cord, or chemical meningitis. Administration of phenylbutazone (4.4 mg/kg PO every 24 hours) 1 day before through 1 day after myelographic examination attenuates fever and depression associated with chemical meningitis.

35.50.5 Treatment

Conservative management of CVSM-affected horses consists of administration of antiinflammatory therapy (glucocorticoids, dimethyl sulfoxide [DMSO], and nonsteroidal antiinflammatory drugs [NSAIDs]) and exercise restriction. Antiinflammatory therapy alone may reduce the edema associated with spinal cord compression; however, full recovery is unlikely without dietary or surgical intervention.

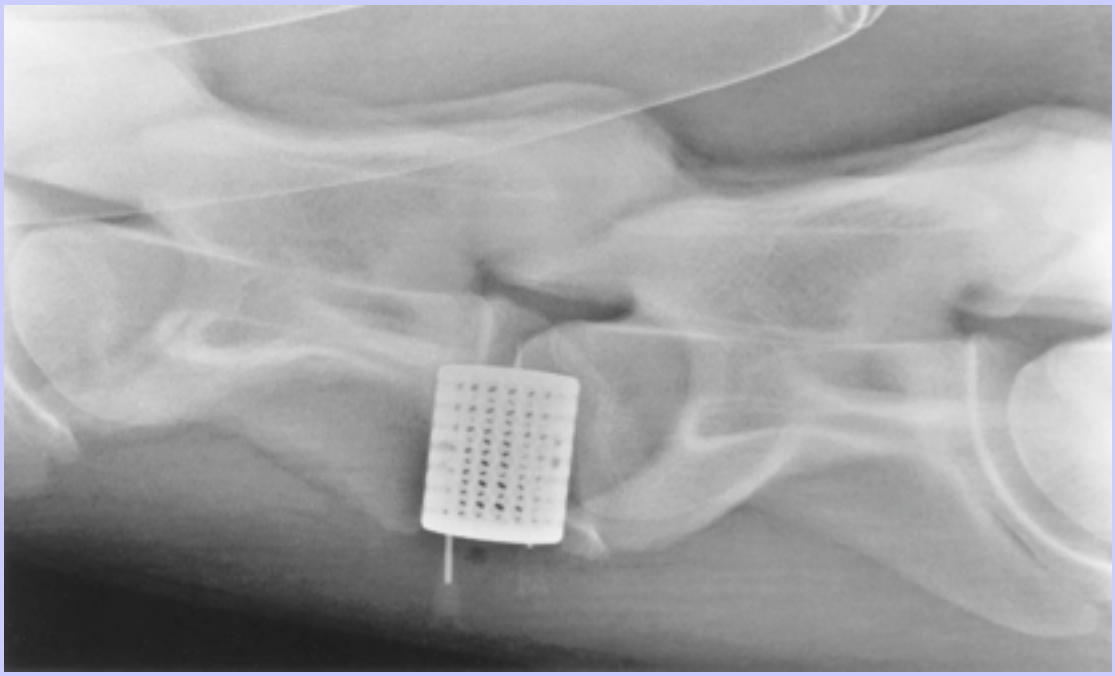
The most successful conservative treatment option for CVSM-affected foals (<1 year of age) is the "paced diet" program.[1889] This program is designed to correct endocrine imbalance associated with high-carbohydrate diets. After a carbohydrate meal, high serum insulin and low serum thyroxine concentrations promote cartilage proliferation and retention without promoting maturation. This dietary program is restricted in energy and protein (65% to 75% of National Research Council [NRC] recommendations) but maintains a balanced vitamin and mineral intake (minimum 100% of NRC recommendations). Vitamins A and E are provided at three times the NRC recommendations, and selenium is supplemented to 0.3 ppm. Roughage is provided by pasture or low-quality grass hay (6% to 9% crude protein). Solitary stall confinement is recommended to minimize repetitive spinal cord compression from dynamic instability.

Horses with cervical pain and forelimb lameness caused by cervical vertebral arthropathy may benefit from intraarticular administration of corticosteroids and chondroprotective agents.[1870,1890–1892] Arthrocentesis of the cervical vertebral articulations (facets) is performed with ultrasound guidance using a 6-inch, 18-gauge spinal needle in the standing, sedated, or recumbent horse.[1893] The cranial facet of the caudal vertebrae will appear superficial to the caudal facet of the cranial vertebrae. The articular space is accessed at the cranioventral opening of the articular facet, which is angled approximately 60 degrees from the ultrasound beam. The needle should be introduced 5 cm cranial to the facet and inserted at a 30-degree angle to the skin surface. Joint penetration should be confirmed by aspiration of synovial fluid. If the neck is extended, the transverse process of the cranial vertebrae may obscure the path to the articulation. Intraarticular triamcinolone (6 mg/joint) or methylprednisolone (100 mg/joint) has produced a positive clinical response in approximately 50% of horses with arthrosis of the articular processes. An antimicrobial agent (e.g., amikacin, 250 mg) can be administered prophylactically with intraarticular corticosteroids or chondroprotective agents. The goal of intraarticular antiinflammatory therapy should be to improve cervical mobility, reduce cervical pain, and eliminate forelimb lameness. It is unlikely that intraarticular therapy will significantly improve clinical signs of spinal ataxia.

1071

1072

Fig. 35-31 Intraoperative radiograph of third and fourth cervical vertebrae during cervical vertebral interbody fusion. The stainless steel basket is placed in the ventral aspect of the vertebral bodies, spanning the intervertebral disk and vertebral endplates, at the C3-C4 articulation.



Surgical intervention is the most widely reported treatment for CVSM and is indicated to stop repetitive trauma to the spinal cord.[1894–1897] The goals of surgical intervention are to stabilize the cervical vertebrae and decompress the spinal cord. Cervical vertebral interbody fusion (ventral stabilization) provides intervertebral stability for horses with dynamic spinal cord compression. The affected cervical vertebrae are fused in the extended position to provide immediate relief of compression and prevent repetitive spinal cord trauma (Fig. 35-31).

Dorsal laminectomy (subtotal Funkquist type B) is performed to decompress static lesions by removing portions of the dorsal lamina, ligamentum flavum, and joint capsule at the compressed site.[1895] This procedure provides immediate decompression of the spinal cord; however, fatal postoperative complications may occur.[1896] Interbody fusion in horses with static compression causes remodeling and atrophy of the articular processes, resulting in delayed decompression of the spinal cord over weeks to months.[1898] Decompression is immediate with dorsal laminectomy. Because of the relative safety of interbody fusion, however, some surgeons believe it is the technique of choice for both dynamic and static compressive lesions.[1896]

Cervical vertebral interbody fusion improves the neurologic status in about half the horses with CVSM, with some horses returning to athletic function.[1894,1896] An improvement in one or two neurologic grades of five is

expected. The most important patient factor for determining the postoperative prognosis is the duration of clinical signs before surgical intervention; horses with clinical signs for less than 1 month before surgery are more likely to return to athletic function than those with clinical signs for longer than 3 months.[1896] In addition, the number of compressive sites, severity of the compression, and severity of postoperative complications contribute to the long-term prognosis.[1870] Subtotal laminectomy and cervical vertebral interbody fusion for static compression of the caudal cervical vertebrae are associated with fatal postoperative complications, including vertebral body fracture, spinal cord edema, and implant failure.[1896]

Postoperatively, horses should be maintained on strict stall rest for 3 weeks and fed from a hay net to minimize motion at the surgical site. Intraarticular injection of the intervertebral articulations with corticosteroids immediately after surgery may lead to more rapid decompression.[1870] The duration of convalescence and rehabilitation after cervical vertebral interbody fusion is approximately 6 to 12 months. An individualized exercise program, determined by the projected use of the horse and the animal's neurologic status, should be designed to promote muscular strength. Extended exercise at slow speed, including ponying and lunging on inclines, is recommended during rehabilitation. A neurologic examination should be performed to determine the horse's ability to return to athletic function after surgery. It is unlikely that significant improvement in neurologic status will occur beyond the 1-year postoperative period.[1896]

35.51 EQUINE DEGENERATIVE MYELOENCEPHALOPATHY

35.51.1 Definition and Etiology

Equine degenerative myeloencephalopathy (EDM) is a symmetric, noncompressive spinal cord disease of young horses characterized by demyelination in the dorsal funiculi of the cervical spinal cord and in the brainstem.[1899] A similar disorder in which lesions are found only in the gracile and cuneate nuclei of the medulla oblongata also has been described, termed *neuraxonal dystrophy* to differentiate it from the more common EDM.[1900] Signs most often develop in horses less than 1 year of age (mean, 5 months), but onset of signs can occur as late as 12 years.[1899,1901] The incidence of EDM in Arabian horses is disproportionately high.[1899] The disease has been recognized in zebras, donkeys, Welsh ponies, and horses of the Przewalski, thoroughbred, standardbred, Appaloosa, quarter horse, Paso Fino, Paint, Haflinger, Norwegian Fjord, Trakehner, Hanoverian, and Morgan breeds.[1902–1909] EDM has also been observed in Mongolian wild horses.[1903]

The disease may be related to a dietary deficiency of vitamin E, but EDM also has a familial pattern of distribution. These observations suggest a genetic etiology, but the mode of inheritance is not clear.[1910]

35.51.2 Clinical Signs

Affected horses show a symmetric proprioceptive (sensory) ataxia characterized by knuckling, stumbling, circumduction, abduction, interference, abnormal limb protraction, spasticity, hypermetria, and inability to turn sharply or lift the inside forefoot during sharp turns. When the animal is forced to turn sharply in a circle, the inside hindfoot pivots instead of lifting off the ground. Affected animals appear clumsy and cannot stop rapidly from a gallop. When stopped suddenly, they step on the rear of the forelimbs and end in a dog-sitting posture. Affected animals usually have severe conscious proprioceptive deficits that can be detected by postural placement tests. Some patients are unable to back or move easily down an incline. They may fall or stumble

when light pressure is applied to the tuber coxae or withers. Signs are often more severe in the hindlimbs than in the forelimbs; in some cases, signs are only apparent in the hindlimbs.[1911]

Other clinical signs that may be observed with EDM are deficits of the local cervical and cervicoauricular reflexes, absence of response to the "slap test"[1912] (see Chapter 8), and paralysis of the laryngeal adductor muscles. Absence of these findings, however, does not completely exclude a cervical spinal cord disease.[1913] In rare cases, animals with EDM may present in acute recumbency without a prior history of neurologic disease (M.O. Smith, unpublished data).

The most important differential diagnoses for EDM are cervical stenotic myelopathy ("wobbler syndrome"), equine herpesvirus myeloencephalopathy, and equine protozoal myeloencephalitis.

35.51.3 Clinical Pathology and Radiographic Findings

EDM is best differentiated from cervical stenotic myelopathy by plain and contrast radiographic examination of the spinal column. The cervical spinal canal, CSF protein concentration, and white blood cell count of horses with degenerative myeloencephalopathy are normal. Serologic testing and CSF analysis is indicated to rule out herpesvirus and protozoal myelopathies. The acute clinical course of herpesvirus myelopathy and the presence of signs such as cranial nerve involvement and lower motor neuron lesions in protozoal disease help to differentiate these entities from EDM. The plasma vitamin E concentration may be below the reference range (300 to 1050 µg/dL) in some unsupplemented affected horses.[1903,1904] For analysis, optimal methods of blood collection include collection of unhemolyzed blood in a clot tube and storage in an upright position in a refrigerator. The refrigerated specimens should not be allowed to contact rubber stoppers and should not be stored for longer than 72 hours unless the red cells are removed and the plasma is gassed with nitrogen and frozen at −16° C (3.2° F). The concentration of vitamin E in specimens handled in this manner remains constant for at least 3 months.[1914]

35.51.4 Pathophysiology

Some suggest that EDM is associated with a low plasma concentration of vitamin E from 6 weeks to 10 months of age.[1904,1915,1916] Oral absorption of vitamin E does not appear to be deficient in affected horses.[1916] Vitamin-replete, clinically normal horses have a plasma concentration ranging from 1.7 to 9.5 µg/mL; vitamin E concentration is approximately 2 µg/mL higher in the spring and summer than in winter. Horses fed diets that lack fresh green forage have a low plasma concentration of vitamin E. Such diets include poor-quality, sun-baked hay and pelleted rations. In one study testing vitamin E supplementation, the case-attack rate declined from 40% to 10% in the first year after supplementation, and the severity of disease in subsequent foal crops was diminished. Moreover, supplementation of five affected horses with 6000 IU vitamin E daily improved their neurologic condition. Horses' susceptibility to development of low vitamin E concentrations also appears to be age related. Foals sired by affected stallions tend to have lower plasma α-tocopherol concentrations than those sired by normal stallions. These lower concentrations are first noted by 6 weeks of age, but the differences disappear by 10 months. The causes of the differences in the two groups of animals are unknown. An alternative explanation for the role of vitamin E in EDM is a defect in vitamin E absorption, transportation, or metabolism.[1980] The nature of such a defect has yet to be elucidated.

Vitamin E deficiency is apparently not the sole etiologic factor in EDM, however, because one report documented normal vitamin E levels in the sera of 40 affected horses examined at a veterinary hospital.[1917]

Subsequent epidemiologic studies indicated that risk factors for the disorder include heredity, application of insecticides on foals, exposure to dirt lots without pasture, and exposure to wood preservatives. Access to green pasture had a protective effect on foals.[1916] This study may indicate that the changes in the central nervous system are related to the patient's inability to respond adequately to oxidative stress such as phenols, anthelmintics, and insecticides. The key role of vitamin E as an antioxidant may explain the link between the disparate etiologies proposed for EDM.

The deficiency occurs most often in related horses, suggesting a genetic predisposition.[1900,1916] The importance of heredity in the development of EDM is supported by studies in a number of breeds, including Appaloosa, Haflinger, and Morgan horses.[1900,1907,1918] A higher incidence has been documented in both foals sired by certain stallions and foals born to mares that already produced an affected foal.[1901,1904] However, the mode of inheritance is not clear.

Recent studies have indicated that a defect in axonal transport of proteins, particularly certain proteins vital to synaptic function, may be a key mechanism in the pathogenesis of EDM.[1919]

35.51.5 Pathology

The microscopic lesions are present throughout the spinal cord, involving both white matter and gray matter, and are most pronounced in the dorsal spinocerebellar tracts.[1903] These lesions include diffuse axonal degeneration of ascending and descending spinal cord funiculi and prominent myelin loss. Gliosis and astrocytosis develop in response to myelin breakdown. Horses with acute, rapidly progressive disease have evidence of active myelin destruction and vaculoation, whereas those with a more gradual course of disease have prominent astrogliosis. Considerable accumulation of lipofucsin-like pigment has been reported in some affected horses.[1909] The form of EDM termed neuraxonal dystrophy (e.g., in Morgan horses) is characterized by lesions almost entirely confined to the lateral caudate nucleus in the medulla. Because of the clinical signs in these horses, however, it is suspected that subtle lesions may be present within the spinal cord.

35.51.6 Treatment and Control

EDM is a chronically progressive disorder, although the clinical signs may stabilize after 2 to 3 years of age. The signs are irreversible, and most patients eventually are euthanized because they present a hazard to other livestock and humans.

Some improvement of clinical signs has been reported in horses treated with vitamin E. The current recommended vitamin E level for horse feed is 80 to 100 IU/kg/day.[1920] In suspected cases of EDM, supplementation with 6000 IU of D,L-α-tocopherol acetate in feed is recommended, a level that appears to be safe. This dose should be mixed with 60 mL corn oil and fed in 1 L concentrate ration daily.[1920] Once clinical signs are present, the prognosis for complete recovery is guarded to poor. Supplementation has been recommended for foals at risk of developing the disease (e.g., family history of EDM) and foals maintained on poor-quality pasture.[1904,1916]

35.52 EQUINE MOTOR NEURON DISEASE

THOMAS J. DIVERS

In 1990 an acquired neurodegenerative disease of adult horses was first described.[1921] The equine disease appeared similar to one form of human motor neuron disease, amyotrophic lateral sclerosis (ALS, or Lou Gehrig's disease). Equine motor neuron disease (EMND) is the only naturally occurring animal model for ALS. Experimental studies have revealed that the disease occurs secondary to chronic vitamin E deficiency and oxidative neuronal cell injury.[1922] Reports of this disorder are now almost worldwide.

35.52.1 Clinical Signs

Affected animals are adults with a mean age of 9 years (range, 2 to 23 years).[1923] Clinical signs vary depending on the stage or duration of the disorder; therefore the signs are best summarized by dividing the disease into subacute and chronic forms. A subclinical form also occurs, although these cases cannot be currently diagnosed antemortem.

35.52.1.1 SUBACUTE FORM

Horses develop acute onset of trembling, fasciculations, lying down more than normal, frequent shifting of weight in the hindlegs, and abnormal sweating. Head carriage may be abnormally low. Appetite and gait often are not noticeably affected, but some horses have a ravenous appetite. The owner may mention that the horse had been losing weight (loss of muscle mass) for a month before the other signs appeared.

35.52.1.2 CHRONIC FORM

The trembling and fasciculations subside, and the horse's condition stabilizes, but with varying degrees of muscle atrophy. In some cases the atrophy is so severe that the horse looks emaciated. In other cases, muscle mass and fat deposition show noticeable improvement. The tailhead frequently is in an abnormally high, resting position.

35.52.1.3 SUBCLINICAL FORM

Experimental research has proved that horses maintained on prolonged diets low in vitamin E may have subclinical disease. This could have significant implications because unknown to the rider or owner, the affected horse would have diminished strength. Pathology of EMND without clinical signs specific for the disease has also been found in a few yearlings with equine degenerative myeloencephalopathy.

35.52.2 Clinical Pathology

Horses with acute or subacute EMND have mild to moderately elevated levels of creatine kinase (CK) and aspartate transaminase (AST). The serum vitamin E is low (<1 μg/mL) in almost all acute and subacute cases. Levels of α- and γ-tocopherol are low in the gray matter of affected horses. Superoxide dismutase (SOD) activity in red blood cells also is severely decreased, believed to result from increased consumption of SOD. Other clinicopathologic abnormalities may be present in particular individuals, including elevated serum γ-glutamyltransferase (GGT) activity; low vitamin A, β-carotene, and ascorbic acid levels; and high liver iron and spinal cord copper levels. Many horses have abnormal glucose absorption, and some have enhanced glucose utilization.[1924] This supports the observation that many horses have ravenous appetites and that most have normal fat deposition at necropsy.

The protein CSF level is elevated in almost half of affected horses, and intrathecal immunoglobulin G (IgG) is increased in many cases. Increased IgG is thought be a response to neuronal death rather than a primary pathophysiologic event.

35.52.3 Pathophysiology

The sites of lesions in EMND are the ventral horn cells (lower motor neurons) of the spinal cord gray matter; the nuclei of cranial nerves V, VII, and XII; and the nucleus ambiguous; all undergo noninflammatory degeneration. Neurogenic atrophy occurs in muscles innervated by degenerate neurons, particularly those with predominantly type 1 myofibers, which have a higher oxidative requirement than type 2 fibers and thus are more susceptible to oxidative damage. The dysfunction and death of motor neurons is an oxidative disorder, presumably caused by vitamin E deficiency and the resulting inability to protect against oxidative (prooxidant) stress. Clinical signs occur when approximately 30% of the motor neurons are affected.[1925] Some of these neurons may regain function with vitamin E treatment, which may explain why some horses do not have continual progression of clinical signs, as occurs in ALS in humans. Human motor neuron disease, although an oxidative disorder, is more complex that EMND, and the causes have yet to be determined.

35.52.4 Pathology

Gross lesions are limited to pallor of the medial head of the triceps brachii and vastus intermedius muscles. Severe atrophy is present in these muscles and many others, including the sacrocaudalis dorsalis medialis muscle of the tail, which shows severe denervation atrophy and fibrosis. Scattered areas of myofiber necrosis are present in many muscles. A pigment retinopathy[1926] and deposition of lipopigment in the spinal cord vasculature are found in horses with EMND, apparently related to similar pigment depositions in other species with vitamin E deficiency. A vitamin E–supplemented diet may result in resolution of pigment deposition in the spinal cord vasculature but not the retina.

35.52.5 Epidemiology

EMND is a sporadic disease, with only single animals in a barn usually affected, although a few outbreaks of the disease have been reported. All breeds of horse can be affected, as can ponies. The apparent prevalence of EMND in certain breeds probably reflects the prevalence of the breed in specific populations of horses, and no familial or heritable predisposition has been identified. Affected horses usually are housed in facilities with little or no access to pasture for more than a year before signs appear.[1923,1927] The diet of affected animals in North America is deficient in green foodstuffs and frequently consists of pelleted or sweet feed and poor-quality grass hay, without alfalfa or other sources of vitamin E supplementation.[1928,1929] In the United Kingdom a few horses with EMND have been on pasture, have no laboratory or necropsy evidence to support malabsorption, but are deficient in vitamin E.[1930] The explanation for this remains elusive. No other management practices, such as worming and vaccination regimens, insecticide use, amount of exercise, or type of bedding, have been related to development of the disease. The highest prevalence of EMND in North America occurs in the northeastern United States and Canada, although sporadic cases have been reported across the continent. This regional distribution is believed to relate to the frequency of predisposing management practices in high-incidence areas rather than other environmental factors.

35.52.6 Diagnosis

The diagnosis of EMND can be made from the following observations and testing:

1 Epidemiologic information.

a Previous cases in the stable.

b Historic information that suggests the horse might have been without green forage for an extended period (with a few exceptions in the United Kingdom).

1074

1075

2 Clinical signs (see earlier section).

3 Measurement of plasma vitamin E and muscle enzyme levels.

35.52.6.1 MUSCLE OR NERVE BIOPSY

Biopsy of the sacrocaudalis dorsalis muscle is the invasive test of choice, with almost 90% sensitivity and specificity.[1931] The biopsy specimen should be placed in 10% formalin for laboratory submission. A positive result is the finding of characteristic abnormalities, including denervation atrophy of myofibers and scattered myofiber necrosis. Biopsy of the spinal accessory nerve is more technically demanding but is a more sensitive test in chronic cases.[1931,1932] Nerve biopsy requires general anesthesia, whereas muscle biopsy can be performed using a local block in the sedated horse.

Differential diagnoses for EMND include equine protozoal myeloencephalitis, colic, laminitis, botulism, and tying-up.

35.52.7 Treatment

Oral vitamin E supplementation at 5000 to 7000 IU daily may result in improvement in some clinically affected horses, although full recovery is unlikely. This therapy cannot reverse the neuronal death, and all affected horses are permanently weakened. Use of a source of pure vitamin E is preferable to a multi–vitamin-mineral supplement. Natural vitamin E products are preferred over synthetic products, but both will raise serum levels.

35.52.8 Prevention

All horses without green forage (grass of good quality or green hay) for prolonged periods (>1 year) should be routinely tested for the plasma vitamin E concentration and supplemented with vitamin E. If this were a standard policy, most if not all cases of EMND could be prevented.

35.53 SPINAL FRACTURES AND LUXATIONS AND SPINAL CORD TRAUMA

35.53.1 Definition and Etiology

Vertebral fractures are relatively common causes of spinal cord injury in food animals. In horses with various neurologic disorders, however, spinal fractures represented only about 3% of cases in two studies.[1933,1934]

Because of differences in management, temperament, and regional spinal strength, the pathogenesis and predominant anatomic location of spinal injury sites differ among the livestock species.

35.53.1.1

HORSES

In a U.K. study examining 26 horses with spinal fractures, 16 had cervical fractures, 17 had thoracic fractures, five had lumbar fractures, and four had sacrococcygeal fractures.[1935] The vertebrae most often injured were C1, T12, and L5.[1935] Horses with lesions of the thoracic dorsal spinous processes did not show neurologic deficits, whereas a high proportion of horses that had lesions in the lumbar and cervical spine had ataxia or other associated neurologic deficits. Stress fractures of the lumbar vertebral laminae may be common in racehorses, frequently are undiagnosed during life,[1936] and should be considered in the differential diagnoses for poor performance and hindlimb lameness in at-risk animals.

35.53.1.2

RUMINANTS

Fractures of the vertebral column in ruminants may result from abnormal bone mineralization. The common sites of spinal fractures in calves are C2 to C4, T10 to T13, and L3 to L6 vertebrae. Spinal fractures are especially common in 3- to 6-month-old ruminants as a result of nutritional deficiencies, including vitamin D, calcium, and copper. Differentiation of nutritional osteodystrophies from traumatic vertebral fractures is essential, because different preventive measures must be taken for the two conditions. Traumatic cervical vertebral fractures of cattle and small ruminants may be caused by injuries sustained in falls, roadway accidents, butting of other animals, predation, or squeeze chutes.[1937,1938] Spontaneous fractures of vertebrae weakened by developmental defects (hemivertebrae) or spinal abscesses also are common problems in calves. Rarely, pathologic fracture may result from weakening of bone caused by bacterial osteomyelitis.[1939] More often, bacterial infection is a sequela to spinal fracture.

Traumatic luxations or fractures of the atlantooccipital and atlantoaxial joints of pygmy goats may occur when the horns are held during restraint.

Fractures of the lumbosacral spine of cattle are frequently caused by slipping in cemented areas.[1937] Many of the spinal fractures occur during mounting by herdmates exhibiting estral behavior. Thoracolumbar fractures may occur in calves during correction of a dystocia, particularly epiphyseal slippage at the middle to caudal thoracic vertebrae.[1940,1941] The occurrence of spinal fractures during assisted delivery is mainly related to the excessive traction and rotational force used.[1942] Luxation of the sacroiliac joint in the dam may occur with the use of excessive force during manual extraction of a calf. Traumatic lumbar vertebral fractures occur secondary to chronic ankylosing spondylosis in mature bulls and rams.[1943]

Trauma to the spinal cord without spinal fracture can result in concussive damage to the cord, including shearing forces and hemorrhage within the neuropil. Hemorrhage and inflammation around the cord can result in space-occupying lesions that cause clinical signs similar to those resulting from spinal fractures. Prognosis for recovery is generally more favorable with blunt trauma than spinal fractures, although outcome depends on the severity of the injury.

35.53.2 Clinical Signs

The clinical presentation of a spinal fracture varies, depending on the site of the traumatic lesion, severity of the spinal cord compression, and involvement of specific anatomic tracts.

35.53.2.1 CERVICAL SPINE

Acute vertebral fractures are painful, and the patient usually shows some distress in the early stages. Goats may bleat or cry when the spine is manipulated. Horses groan and, if recumbent, thrash wildly. Cattle and sheep may lie on their sides and groan. Animals with noncompressive cervical lesions maintain a stiff neck ("weather vane" attitude), refuse to lower the head, and eat from the ground while kneeling. To prehend food, they often keep the head away from the ground and extend the tongue. These animals have stiff necks and resist passive flexion of the head.[1944] Similar signs may be seen with meningitis. Forelimb lameness with or without obvious neurologic deficits may be the presenting complaint when fractures are fairly stable and cause minimal disruption to the spinal cord.[1945,1946] Cervical fracture should be a differential diagnosis for unexplained forelimb lamenesses.

Animals with severe lesions may be recumbent. Depending on the amount of pain and the secondary complications associated with the disease, the sensorium varies from bright, alert, and responsive to depressed and painful. Recumbent animals may not be able to lift the head from the floor if a high cervical lesion (C1 to C4) is present.[1947] Crepitation may be palpable in some cases. Luxation of the atlantooccipital joint results in asymmetry of the wings of the atlas. These animals often have a wry neck as a result of the twisting forces on the displaced atlas.[1948] Patients with mild lesions of the cervical spine may be able to stand and show varying degrees of ataxia and conscious proprioceptive deficits. Specific gait abnormalities include circumduction, interference, knuckling, incomplete limb protraction, crossing over, and excessive body sway. Animals with high partial cervical lesions may show hypalgesia of the entire body. Bilateral, severely compressive lesions of the cervical spine can result in rapid death from respiratory paralysis if neurologic injury causes paralysis of the phrenic nerve. If the spinal cord lesion is above the C6 segment (C6 to C7 vertebrae), the muscular tone and spinal reflexes (panniculus, triceps, and biceps) are normal to increased in all limbs. If the lesion is located at the C6 to C8 segments, forelimb reflexes are diminished or absent and hindlimb reflexes normal to increased. The panniculus response may be absent on one or both sides of the body if the lesion affects the C8 segment, the origin of the lateral thoracic nerves.

1075

1076

Conscious pain perception in the limbs often is diminished or absent, depending on the amount of damage in the sensory spinal cord tracts. In long-standing cases in which the ventral rootlets or motor neurons of C6 to C8 have been destroyed, the muscles of the neck and forelimbs may become atrophic. Regional or strip sweating may be observed in some horses. The anal tone and tail tone are normal. The bladder may be distended, but the tone of the urethral musculature is normal.

35.53.2.2 THORACIC SPINE

Animals with thoracic trauma have an attitude similar to those with cervical lesions, except that thoracic limbs are normal. Animals with severe spinal cord lesions intermittently lie on their sides and then arise to assume a dog-sitting posture. When lying in sternal recumbency, animals hold the hindlimbs extended rather than in the normal tucked-up position. The spinal reflexes of the forelimbs are normal. A crossed extensor reflex may be observed in the hindlimbs. Depending on the amount of damage to the sensory tracts,

conscious perception of pain in the hindlimbs may be decreased or absent. The tail and anal tones are normal. The bladder is distended, but the tone of the urethral sphincter and penis is normal. Animals with acute lesions of the thoracic spine (<2 days' duration) may display Schiff-Sherrington syndrome.[1949] Forelimb postural reactions are normal but muscular tone is increased, resulting in a stiff forelimb gait. Postural reactions in the hindlimbs are decreased to absent, with normal to hyperreflexic myotactic reflexes (see Chapter 8). Schiff-Sherrington syndrome is rare in large animals. Most animals with thoracic injury have normal to exaggerated spinal reflexes and hypertonia of the rear limbs.

35.53.2.3

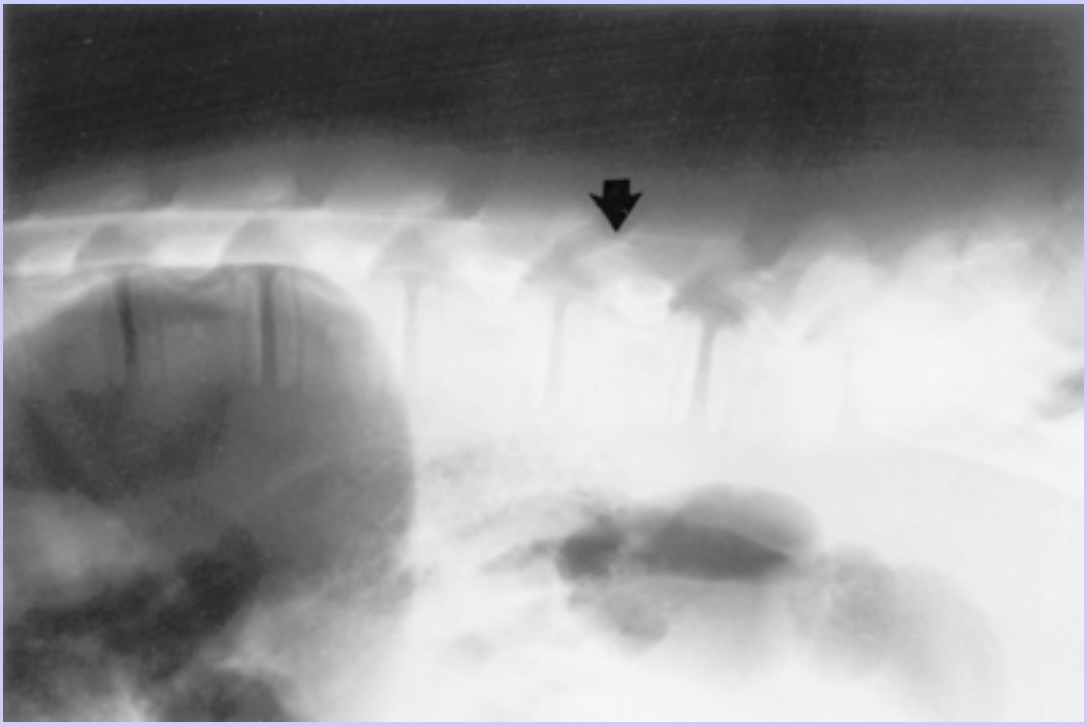
LUMBAR SPINE

Animals with lumbar injury have an attitude, gait, and posture similar to those with thoracic lesions. Fig. 35-32 shows the characteristic posture of a calf with a fracture at the L6 vertebra. Fig. 35-33 illustrates myelographic findings of cord compression at L6. The forelimbs are normal. Lesions at the L1 to L3 spinal cord segments result in normal or hypertonic and hyperreflexic hindlimbs. Conversely, hypotonia and hyporeflexia of the hindlimbs may be seen in animals with lesions at segments L4 to S2.[1950] Marked spasm of the longissimus dorsi muscle has been described in horses with a lesion between the T11 and T12 segments.[1951] Lesions of segments L4 to L6 result in cutaneous desensitization of the medial surface of the rear leg and diminished or absent patellar reflex because of dysfunction of the femoral and saphenous nerves. Lesions of segments L6 to S2 result in desensitization of the hindlimb and diminished withdrawal (flexor) reflexes. The panniculus response is absent when the skin posterior to the lesion is stimulated. Damage to the spinal rootlets may cause regional swelling. Tail tone and anal tone are normal. The bladder is distended, but the sphincter tone is normal.

1076 1077

Fig. 35-32 Characteristic posture of a calf with a compressive fracture of the sixth lumbar (L6) vertebra and hematomyelia. The calf was fed a diet of grass hay and corn and developed nutritional osteodystrophy. Courtesy Dr. R.H. Whitlock.

Fig. 35-33 Myelogram of a calf with nutritional osteodystrophy showing a mild compression fracture of the L6 vertebra and complete obstruction of dye flow posterior to L5 *(arrow)*.



35.53.2.4 SACROCOCCYGEAL SPINE

Lesions of spinal cord segments S1 to S2 result in decreased conscious proprioceptive responses of the rear limbs[1952] and diminished flexor reflexes of those limbs. Anal tone is diminished to absent, and the bladder is distended and hypotonic. The patient is incontinent because of atonia of the urethral sphincter, and urine scalding may be seen over the perineum. The tail is flaccid and paralyzed. The anal sphincter is dilated, and the rectum is filled with dry fecal matter. There may be palpable abnormalities of the pelvis or sacrococcygeal joint. Crepitus of the pelvic bones may be noted when the animal is moved.

35.53.3 Clinical Pathology and Radiographic Findings

Radiography is the usual method of diagnosing a spinal fracture. In young horses, slipped physeal plates are often seen in the atlas.[1951,1953] Shortening of the lumbar vertebrae is consistent with either an oblique overriding fracture of the vertebral body or a compression fracture.[1950,1953] Abnormally shaped vertebrae may signify an anomalous vertebral arch. Myelographic examination may detect stenosis in segments distant from the fracture site.[1954]

Examination of cerebrospinal fluid (CSF) collected through a lumbosacral puncture may be useful for ancillary diagnosis of a spinal fracture. Fracture-induced changes in the CSF may be classified as either acute (0 to 1 day) or chronic (>1 day). The acute changes include diffuse blood contamination, a high red blood cell (RBC) count, a normal to high white blood cell (WBC) count, and a high protein concentration. The CSF changes in patients with more chronic injuries include a normal to slightly increased WBC count, normal to increased RBC count, increased protein concentration, and xanthochromia. These changes are not pathognomonic for spinal fracture, however, so should be interpreted with caution.

35.53.4 Pathology and Pathophysiology

Neurologic dysfunction after spinal trauma is similar to that of brain trauma and is a result of both immediate and secondary events. Immediate causes of injury include shearing forces that result in tearing of tissue, hemorrhage, and impingement of bone fragments on the spinal cord, particularly when the fracture is unstable. Trauma initiates a cascade of secondary biochemical events that further injure nervous system tissue, including adenosine triphosphate (ATP) depletion, which deprives cells of their ability to maintain their ionic environment through the action of sodium-potassium ATPase pumps. Rapid intracellular accumulation of calcium and sodium ions causes cytotoxic edema and neuronal depolarization. Release of the excitatory neurotransmitter glutamate and activation of the arachidonic acid and xanthine oxidase pathways further compound cellular damage. Other injurious substances generated after traumatic injury include nitric oxide, oxygen free radicals, lactic acid, arachidonic acid metabolites, and a variety of cytokines. Local vasogenic reflexes, mostly mediated by α-adrenergic receptors, result in decreased blood flow in the gray and white matter. Platelets aggregate in the hypoperfused capillaries and form microthrombi and infarcts. Regional ischemia caused by hypoperfusion results in lipid peroxidation of the axons, myelin degradation, and demyelination.[1955]

35.53.5 Treatment and Prognosis

It is important to recognize that the radiographic appearance of a spinal fracture is not a reliable prognostic indicator, because the vertebral components are likely to be in a different position from that at the time of injury. Not all vertebral body fractures result in neurologic disease. The prognosis is best judged on the basis of repeated neurologic examinations. Provided the animal is not suffering inhumanely and the pain can be adequately controlled, repeated neurologic examinations should be made over the first several hours. The longer the patient remains recumbent and neurologically impaired, the more unfavorable the prognosis.

The mainstay of immediate treatment of spinal injuries is maintaining whole-body homeostasis, particularly the maintenance of cardiovascular integrity and blood pressure.[1956] Ischemia local to the spinal cord plays a key role in development of the injury, but global cardiovascular failure compounds this effect. Most recoveries from spinal cord contusion occur spontaneously and are not appreciably influenced by drug administration. Some recommend treating acutely affected animals with DMSO (0.25 to 1 g/kg IV in 5% dextrose as a 40% DMSO solution) and dexamethasone (0.1 to 0.2 mg/kg four times daily for 2 to 4 days), but supportive data from controlled studies are not available. Analgesics or tranquilizers should be administered with care to ambulatory patients that have thoracolumbar spinal lesions because an ataxic patient may slip and worsen the spinal cord contusion. If signs of pain are severe, NSAIDs or narcotic analgesics may be administered. Epidural catheterization can be an effective method for delivery of analgesics over several days in animals with severe pain.[1957] In animals with pelvic lesions, the bladder should be evacuated either by manual palpation per rectum or by insertion of a catheter and use of a closed urinary drainage system. Attention to aseptic procedure during

catheter maintenance may reduce the number of iatrogenic bacterial infections. The urine should be cultured and examined repeatedly. Bladder infections should be treated with an appropriate antibiotic. In animals with paralysis of the rectal musculature, the feces should be removed manually. Lubricants (1 to 2 quarts of warm detergent or methylcellulose) may be administered with an enema.

If the spinal fracture appears stable and the animal can stand with assistance, the patient may be placed in a water tank and supported for prolonged periods. Goats are most amenable to treatment for spinal fractures, whereas adult horses and cattle may present insurmountable nursing problems and should be euthanized if they are unable to rise after several days or have intractable pain. Slings are commercially available or can be fashioned from canvas or burlap and wool or cotton. The time spent in the sling varies, depending on the animal's temperament and degree of neurologic dysfunction. Some horses become frantic while suspended in the device and cannot be supported without the risk of severe injury to the patient and the handlers. The sling should not be used for recumbent animals that cannot support themselves while harnessed. Such animals can sustain severe (even fatal) respiratory compromise or secondary myositis. Nevertheless, daily slinging of animals with mild neurologic signs may reduce secondary medical complications and facilitate recovery.

1078

Recumbent cattle should be floated in a tub of warm water. Watertight tubs for use with large cattle are commercially available* (see Down Cows at end of chapter).

Cervical fractures and luxations of small ruminants may be stabilized by incorporation of the head, neck, and anterior thorax in a fiberglass cast. The cast should extend from the middle part of the thorax to the tip of the nose. The feed and water supply of all animals with cervical fractures should be placed so that the animal can reach it without bending the neck. Surgical methods for stabilization of cervical fractures have been described in horses. The effectiveness of such treatments for restoration of neurologic function after traumatic injury or fracture of the spinal column is variable, but good results may be achieved when presurgical signs are mild and the repair is stable.[1958–1961]

Fractures of the dorsal spinous processes, transverse processes, and some small, oblique fractures of vertebral bodies may produce minimal instability of the spine. Such injuries may respond well to conservative treatment, such as stall confinement. Bone sequestra can result in the formation of draining tracts, however, and may require surgical removal to facilitate healing.[1962]

The dietary intake of copper, molybdenum, and calcium should be measured in cattle. If the daily intake is inadequate, the minerals should be fed in supplements. Animals with metabolic bone disease should not be restrained because of the risk of inducing additional pathologic fractures.

35.54 ANKYLOSING SPONDYLITIS OF HOLSTEIN BULLS

Ankylosing spondylitis is an inflammatory disease of joint tissue associated with fusion of lumbar vertebrae in Holstein bulls. Approximately 4% of all Holstein bulls used for artificial insemination are culled each year because of spondylitis.[1963] The clinical onset of the condition is insidious. The first signs of the disorder are a stilted gait, reluctance to move, and dragging of the toes of the rear limbs. Affected bulls are slow to mount teaser dummies for collection. The condition is progressive, and over several months the animals develop paraparesis and ataxia. With mounting, the ankylosed area of the spine may fracture, leading to acute recumbency. Pathologic changes associated with the condition include calcification of the ventral vertebral ligaments between the T11 and L3 vertebrae. The condition appears to be hereditary. All bulls with the condition possess the class I major

histocompatibility complex (MHC) BoLA A8 phenotype. In comparison, the phenotypic frequency of BoLA A8 in the general population of normal Holstein bulls is only 44%.[1964]

35.55 SPINAL ABSCESSES

35.55.1 Definition and Etiology

Most abscesses of the spinal cord originate from a preexisting vertebral body osteomyelitis. The bone usually is infected hematogenously. Extension of bacteria from the lungs, the heart, or a septic injection site is common. Neonates frequently develop vertebral abscesses secondary to septicemia.[1965,1966] Bone lesions may develop from sequestra broken from fractured vertebrae. Epizootics of spinal abscesses can result from injection of contaminated vaccines or mineral supplements near the spinal column. Similarly, spinal abscesses may be seen along with other diseases in groups of animals that are immunocompromised, such as cattle with bovine immunodeficiency virus infection.[1967] Infectious agents isolated from spinal abscesses of ruminants include *Corynebacterium pseudotuberculosis, Aracanobacterium pyogenes, Mannheimia haemolytica, Staphylococcus aureus,* and *Fusobacterium necrophorum*.[1965,1968–1970] Agents typically found in vertebral infections of foals include β-hemolytic streptococci, *Salmonella* species, *Actinobacillus equuli, Escherichia coli, Rhodococcus equi,* and *Klebsiella pneumoniae*.[1970–1974] Agents less often associated with vertebral body osteomyelitis of horses and cattle include *Mycobacterium bovis, Mycobacterium avium, Aspergillus* species, *Eikenella corrodens,* and *Brucella abortus*.[1975–1977] In rare cases, septic arthritis of the atlantooccipital joint may result from extension of a mycotic guttural pouch lesion.[1978,1979]

If the infectious agent remains localized in the vertebral body, the patient usually shows signs consistent with a transverse myelopathy. If the infection erodes through the dura mater, the animal develops signs of septic meningitis. If the bone infection is extensive, the vertebrae may fracture suddenly, resulting in signs characteristic of spinal trauma.

35.55.2 Clinical Signs

The neurologic deficits of animals with vertebral body abscesses without pachymeningitis are similar to those described previously for spinal fractures.[1969] Animals with mildly compressive cervical abscesses show a characteristic “weather vane” attitude, appear stiff, and are reluctant to eat food from the ground.[1969,1971,1972] Ruminants with this lesion hold the neck in extension and attempt to prehend the food with the tongue while the head is held more than 30 cm (12 inches) from the ground.[1969] Additional signs of spinal abscess include heat, pain, swelling, or crepitus over the affected areas and associated signs of bacteremia. Abscesses in the thoracolumbar spine cause hindlimb weakness and ataxia of variable severity, from mild gait abnormalities to complete recumbency. Stud males may be unable to breed because of weakness and pain.[1980] Animals with pachymeningitis show characteristic signs of meningeal inflammation such as hyperesthesia, intermittent spasmodic muscle contractions, and recurrent profuse sweating[1971,1975] (see earlier section on meningitis). Differential diagnoses include trauma, aberrant parasite migration, tumor and pathologic fractures, hemorrhage into or around the spinal cord (e.g., postanesthetic myelopathy), myopathies, caprine arthritis-encephalitis, and fibrocartilaginous embolism.[1981] Spinal abscesses can be mistaken for other painful conditions, such as orthopedic disorders or traumatic reticuloperitonitis.[1982]

35.55.3

Clinical Pathology and Radiographic Findings

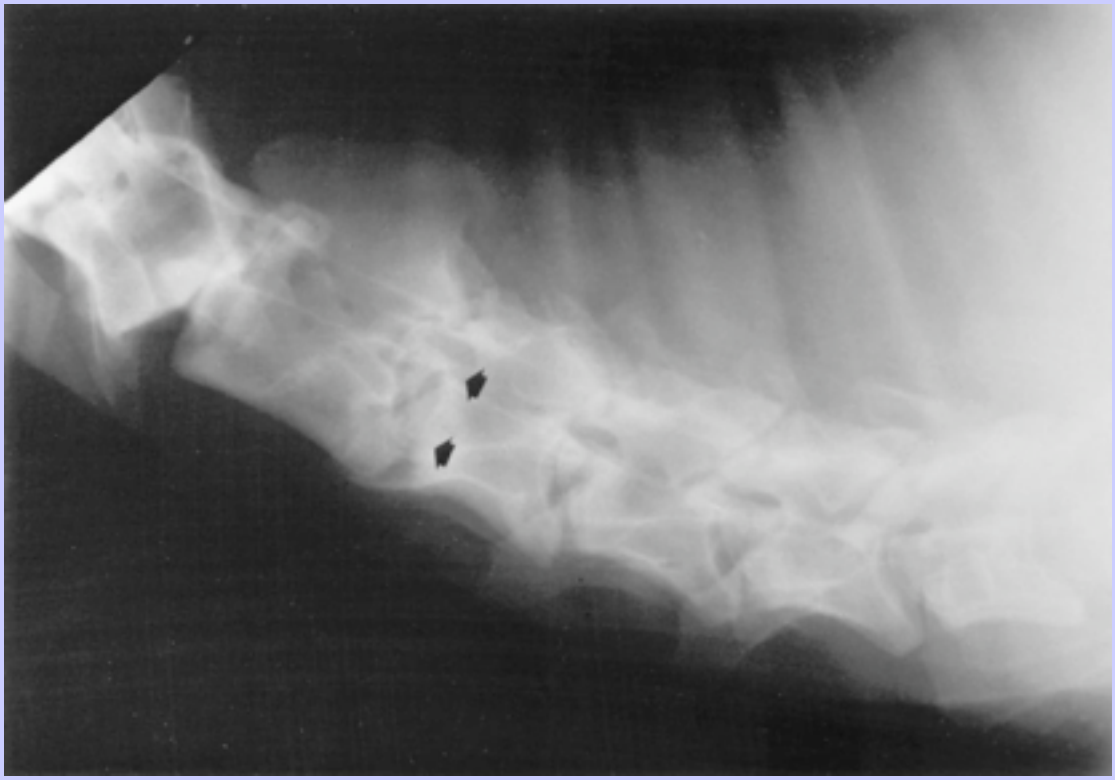
Radiographs are the best method for obtaining a definitive diagnosis of spinal abscessation. A random pattern of hyperlucency and increased bone density characteristic of osteomyelitis is seen in the affected vertebrae, with or without adjacent soft tissue mass lesions indicative of abscessation[1976,1983] (Fig. 35-34). Diskospondylitis usually results in detectable osteolysis in the intervertebral joints.[1971] Occasional cases of extradural abscesses without radiographic evidence of osteomyelitis have been described in calves and lambs.[1331] Nuclear scintigraphy can be used when the bone lesions are not well defined in plain film radiography.[1977] In addition, myelography can be used to detect the specific site of the spinal cord compression.

A complete blood count (CBC) may indicate the presence of a chronic inflammatory focus. Specific changes in the CBC include hyperfibrinogenemia, neutrophilia, monocytosis, nonresponsive anemia, and left shift. The plasma globulin levels are increased in adults but may be increased or decreased in neonates, depending on the adequacy of colostral immunoglobulin transfer.

1078

1079

Fig. 35-34 Cervical radiograph of a sheep with osteomyelitis and diskospondylitis at the C2-C3 intervertebral space *(arrows)*. The sheep recovered fully after application of a full-length cast of the head, neck, and trunk and after continuous therapy with parenteral penicillin G for 1 month.



The changes in the cerebrospinal fluid (CSF) depend on the location of the abscess in the nervous system tissue and the meninges. Changes are present in CSF caudal to the lesion, but not cranial to the lesion; thus, CSF should be obtained by lumbar puncture and not cisternal puncture.[1981] In most cases the abscess does not infiltrate through the pachymeninges, and the CSF is normal or shows xanthochromia and mild increases in the protein concentration (60 to 120 mg/dL), with mild to no increase in nucleated cell count.[1984] The CSF of animals with pachymeningitis contains high numbers of WBCs (>100 neutrophils/dL) and a greatly increased protein concentration (>200 mg/dL). The CSF may clot after collection because of high concentrations of fibrinogen. Bacteria may be observed in a Gram-stained smear of CSF sediment. Horses with spinal brucellosis may have a rising serum agglutination titer or one above 1:160.[1975] Because of a high number of nonspecific reactions in equine sera, titers below 1:40 are considered nondiagnostic.[1985] Horses with spinal tuberculosis may be identified by an intradermal skin test using purified protein derivative or tuberculin.[1976]

35.55.4 Pathophysiology

Hematogenously derived abscesses arise because of embolization of septic thrombi into the metaphyseal arteries. These vessels have a sluggish blood flow because they become tortuous as they approach the physis. The metaphyseal vessels communicate with the ventral vertebral plexus, which in turn drains into the post cava, the portal vein, and the pulmonary veins. The ventral vertebral plexus does not have valves; blood flow reverses with an increase in abdominal or pleural pressure. Regurgitated blood from infected sites in the body cavities showers the vertebrae and spinal cord with bacteria.[1968,1977]

35.55.5 Necropsy Findings

The most common sites of involvement are the costovertebral and intervertebral articulations and the vertebral body epiphyses.[1986] Lumbar vertebrae frequently are involved. The bone is uneven, deformed, and softened. The abscessed area is interspersed with calcified trabeculae and pockets of necrotic debris. Sequestration of necrotic bone may be seen in some cases. The meninges may be adherent to the abscessed site, and occasionally a fistulous tract may be seen from the center of the abscess pocket to the subarachnoid space. In other cases the abscess is compartmentalized away from the CSF, but the proliferating bone impinges on the spinal cord.

35.55.6 Treatment and Prevention

If spinal abscessation is recognized early, prolonged antimicrobial therapy generally is effective. Selection of the appropriate antimicrobial agents should be based on the results of cultures from the patient's blood, urine, feces, and CSF. When bacteriologic culturing is inconclusive, a broad-spectrum antimicrobial should be chosen. Amikacin (7.5 to 10 mg/kg IM four times daily) or gentamicin (1 mg/kg IM three times daily) combined with potassium penicillin G (10,000 IU/kg IV three or four times daily) should be administered. After 1 or 2 weeks of this therapy, a trimethoprim-sulfonamide combination (2 to 3 mg/kg trimethoprim, 10 to 15 mg/kg sulfadiazine PO twice daily) in horses or procaine penicillin G (10,000 to 20,000 IU/kg SC or IM daily) in cattle can be administered for 2 to 3 months.

Small ruminants with cervical diskospondylitis may show a good response after 2 to 4 weeks of procaine penicillin G (10,000 IU/kg IM twice daily). Phenylbutazone, flunixin meglumine, or aspirin may be administered for pain relief. Immobilization of the head and neck in a fiberglass cast extending from the thorax to the nose may provide support to smaller patients with a cervical abscess. Surgical drainage of the abscess and

curettage of the necrotic bone may be feasible in smaller animals with sufficient economic value to justify the procedure.[1974,1987] Surgical intervention in adult cattle and horses is usually difficult because of the size of the epaxial musculature and the inaccessibility of the spine in large animals.

35.56 SPINAL TUMORS

With the exception of lymphosarcoma, spinal tumors in domestic animals are rare. Tumors reported to invade the spinal cord of horses include lymphosarcoma, plasma cell myeloma, meningioma, ependymoblastoma, fibrosarcoma, schwannoma, melanoma, carcinoma, angioma, angioblastoma, ganglioglioma, and neurofibroma.[1988–1999] The most common tumor of the spine of ruminants is lymphosarcoma, but others, such as embryonal neuroectodermal tumors, have been reported.[2000,2001]

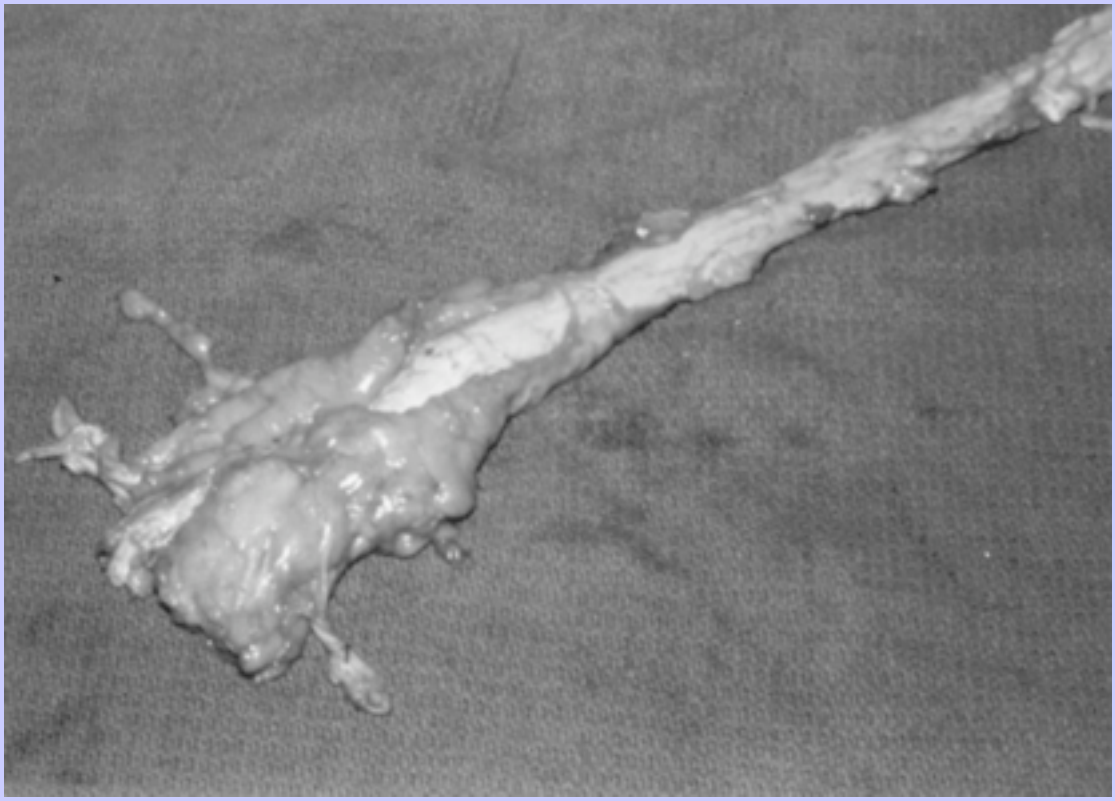
1079
1080

35.56.1 Clinical Signs

The clinical signs of tumorous invasion are indistinguishable from those described previously for spinal fractures. The onset of the neurologic dysfunction varies. Some neurofibromas, melanomas, and lymphosarcomas invade centripetally along the peripheral nerve rootlets. These patients develop slowly progressive dysfunction of the peripheral nerve or spinal cord, which eventually leads to tetraplegia or paraplegia (Figs. 35-35 and 35-36). In rare cases the onset of tetraplegia in cattle with a neurofibroma or lymphosarcoma may be peracute and unaccompanied by prodromal neurologic symptoms. Lymphosarcoma has a predilection for the lumbar segments of the spinal cord and the cauda equina in cattle over 5 years of age. A diagnosis of tumorous spinal invasion should be considered in cases of progressive neurologic disease characterized by flaccid tail and anus, dysuria, urine scalding, distended bladder, perineal analgesia or anesthesia, and paraparesis. Although most animals with spinal tumors are mature to older adults, immature animals can be affected rarely, mainly by embryonal tumors.[1994,1999–2001]

Fig. 35-35 Characteristic appearance of a paraplegic cow with lymphosarcoma of the L6 to cauda equina spinal rootlets and the cauda equina. Courtesy Dr. R.H. Whitlock.

Fig. 35-36 Spinal cord from a cow with lymphosarcoma. The mass is an accumulation of neoplastic lymphocytes that surround the spinal rootlets, filum terminale, and cauda equina.



35.56.2 Clinical Pathology

Examination of CSF may be useful when the tumor has infiltrated the cauda equina and is located in the lumbosacral cistern. In these cases, tumor cells may be biopsied as the needle is inserted into the lumbosacral space. In other cases the CSF may be normal, or albuminocytologic dissociation can be expected (elevated CSF protein with normal to mildly elevated nucleated cell count) with or without variable degrees of hemorrhage and xanthochromia. After necropsy, various immunohistochemical techniques can be used to identify the tumor type when routine histologic examination is insufficient.[2000,2001]

35.56.3 Treatment

There is currently no treatment for most spinal tumors of large animals. One study reported survival of 57 days after three treatments with L-asparaginase at 10,000 IU/mm^2. The body surface area was estimated using the following formula:

$$\text{Surface area } (m^2) = \text{Body weight}(g)^{2/3} \times 10^b \Big/ 10^4$$

where 10^b is a constant that is routinely used for the calculation of surface area in dogs.

The nearly 2-month period of survival allowed the investigators to successfully superovulate the cow. When treating food animals with L-asparaginase, the benefits of the antimetabolite drug must be weighed against the potential for teratogenicity of the fetus, toxicity for humans, and the certainty of relapse in the patient.[2002]

35.57 CEREBROSPINAL NEMATODIASIS

Migration of nematodes and insect larvae through the central nervous system (CNS) can cause acute CNS disease in all species of domestic livestock. The condition occurs in most countries. Parasitic agents that have been reported in the CNS of horses include *Micronema deletrix, Hypoderma lineatum, Hypoderma bovis, Strongylus vulgaris, Draschia megastoma, Setaria* species, and hydatid cysts.[2003–2028] In cattle the condition is caused principally by *Setaria* species and *Hypoderma bovis*. Small ruminants that share pastures with the white-tailed deer may become infected with the meningeal worm *Parelaphostrongylus tenuis*.[2013–2015]

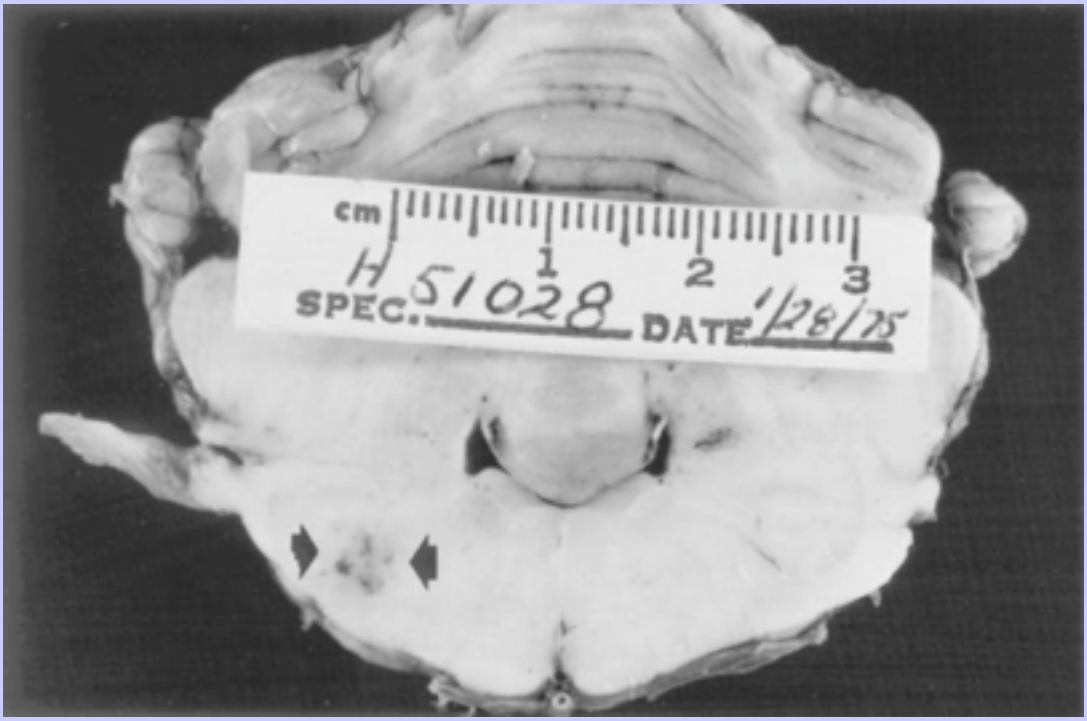
These parasites can attack any region of the CNS, but most clinical cases result from lesions of the brainstem and spinal cord. The clinical signs are similar for all parasitic CNS infestations and include tetraplegia/tetraparesis, paraplegia/paraparesis, asymmetric conscious proprioceptive deficit, hyperreflexia/areflexia, anesthesia or analgesia of dermatomes, and neurogenic atrophy. Cranial nerve deficits may be seen if the parasites migrate through the brainstem. The following sections discuss specific parasitic syndromes in livestock.

35.57.1 HORSES

35.57.1.1 *Strongylus vulgaris* Migration

Migration of *S. vulgaris* in the CNS causes two major clinical syndromes: acute embolization of parasitic emboli and slow perivascular migration of living parasites in the CNS. The two forms have a common pathogenesis. Aberrantly migrating fourth-stage or fifth-stage larvae in the intima of the aorta or left ventricle damage the endothelium, stimulate the clotting cascade, and cause formation of a thrombus that often contains the parasitic larva.[2020] Embolization of the thrombus to the brain results in fulminating encephalitic signs.[2009] As the embolus is degraded, the parasite migrates from the blood vessel into the CNS, resulting in the progressive brainstem disease. The cranial brainstem (diencephalon) is most often affected. The thrombosis and migration are accompanied by multifocal infarction, edema, hemorrhage, and necrosis[2007] (Fig. 35-37). Microscopic findings include linear tracts of hemorrhage lined by neutrophils, macrophages, eosinophils, and reactive glial cells. Anesthesia of the hindquarters has been described in some affected horses.[2010] Donkeys are also susceptible to the aberrant migration.[2029] CSF changes associated with *S. vulgaris* migration in equids include xanthochromia, refractive index over 1.3353, protein concentration ranging from 32 to 550 mg/dL, and increased WBC count (42 to 10,000/μL). The differential counts range from 70% to 80% neutrophils, 12% to 19% mononuclear cells, and 1% to 2% eosinophils.

Fig. 35-37 Parasitic lesions in the brainstem of a horse. The *arrows* indicate the major lesion, but other, smaller lesions are distributed over the entire brainstem. Courtesy Dr. R.H. Whitlock.



35.57.2 ## *Hypoderma lineatum* and *Hypoderma bovis* (Warble Flies)

Hypoderma lineatum and *H. bovis* are parasites that typically affect cattle but occasionally migrate aberrantly in the horse. Warble flies hatch from pupae in the early spring and mature during the summer. The flies deposit the eggs of *H. lineatum* on the lips, where they hatch and are swallowed. The ingested worms burrow through the intestine and along the adventitia of blood vessels until they reach the CNS.[2008] The flies deposit the eggs of *H. bovis* on the legs, where they hatch and burrow into the skin. The subcutaneous parasites then migrate as first-instar larvae to the spinal column, where they penetrate the epidural space along the peripheral nerves.[2004] Peroneal nerve paralysis from a local parasitic invasion has been reported in a pony.

35.57.3 ## Micronema deletrix

Micronema deletrix is thought to be a free-living rhabditid nematode that gains access to the CNS by penetration through the skin of the face and the lips, gums, and tongue.[2005,2006] The parasites migrate into the brain through the vascular system and cause diffuse encephalitis. Nematodes are found in the tunica adventitia and tunica media of blood vessels.[2005] Clinical signs of *M. deletrix* depend on the localization of the parasite. Spinal cord invasion is apparently less common than migration through the brainstem, cerebellum, thalamus, forebrain, and deeper layers of the cerebral cortex. Clinical signs include asymmetric ataxia, loss of conscious

proprioception, depression, behavioral changes, propulsive walking, head pressing, head tilt, circling, nystagmus, recumbency, convulsions, and coma. Affected animals may have granulomatous masses in the nares, pharynx, and maxilla. These could be helpful in formulating a differential diagnosis when parasitic migration is suspected. CSF changes in affected horses include pleocytosis (25 to 80 nucleated cells/μL), a normal to high protein concentration (69 to 114 mg/dL), and xanthochromia.[2003] The cellular types were mostly lymphocytes and macrophages ranging from 78% to 91% of the nucleated cells. Eosinophils were observed in the CSF of one horse.

35.57.4 Draschia megastoma

Draschia megastoma has been found in the brainstem of a horse from the southern United States.[2011] The adult worm is embedded in a pyogranulomatous lesion of the equine stomach, and the eggs are shed into the stomach. They hatch in the small intestine to form first-stage larvae, which are passed in the feces and ingested by the larvae of *Musca* flies. The third-stage larvae migrate to the mouthparts of the fly and are deposited on the mucous membranes of the host as the fly feeds.

35.57.5 Setaria

Setaria parasites are common filarid parasites of cattle that migrate aberrantly when they infect horses, sheep, or goats. These parasites have a worldwide distribution, and clinical cases are especially common in India and the Orient, where the common name for the disease is “kumri” (weak back).[2025] There are at least four *Setaria* species, of which *S. equina, S. digitata,* and *S. labiatopapillosa* are most common. The parasite is found in the connective tissues and peritoneal cavity of cattle, where it produces circulating microfilariae. Mosquitoes and possibly other bloodsucking insects become infected by the microfilariae and thus transmit the parasite.[2024] The parasite has a predilection for the spinal cord in horses. The clinical signs of reported cases include hypotonic tail, bladder paralysis, ataxia, and conscious proprioceptive deficits.[2012] Changes in the CSF associated with *Setaria* infestation include xanthochromia, pleocytosis (25 to 84 cells/dL), and a slightly increased protein concentration (~114 mg/dL). The cells of one horse contained a small proportion of eosinophils and basophils, but this finding was inconsistent with other reports.[2003]

35.57.6 SHEEP AND GOATS

35.57.6.1 Setaria

The infection caused by *Setaria* species in sheep and goats is similar to that described previously for horses.

35.57.7 Parelaphostrongylus tenuis

Disease caused by *P. tenuis* occurs predominantly in sheep and goats of the northeastern United States and western Canada.[2013,2016,2018,2019] The case-attack rate ranges from 10% to 59%.[2014] The disease appears to be spreading because of the increased range of the primary host, the white-tailed deer. Migration of the parasite in the CNS of deer is relatively innocuous, but aberrant migration occurs in domestic small ruminants. The result of this migration is severe signs of spinal cord and brainstem disease.[2014] The life cycle of the worm is complex. Adult worms are found in the cranial subarachnoid space, venous sinuses, and spinal subarachnoid

space of the deer, where they reproduce.[2015] Eggs are deposited into the venous blood and migrate into the lungs, where they embryonate. The larvae penetrate into the airways and are coughed into the pharynx, swallowed, and passed in the feces. They then penetrate into snails and slugs. Sheep and goats are infected when they eat the snails. After ingestion by the ruminant, the larvae penetrate the gastrointestinal wall and enter the CNS by migration along the nerve rootlets. Because of the complex life cycle of the parasite and the indirect life cycle in invertebrate hosts, the neurologic disease in sheep and goats is seen exclusively in late fall and winter. The pathologic lesions of the CNS of affected animals include asymmetric irregular tracts of disrupted necrotic tissue with macrophage infiltration. Coiled larvae occasionally may be seen in the tissues of some affected animals and may be excreted in the feces; however, these are difficult to distinguish from the larvae of *Müllerius* worms.

The clinical signs of *P. tenuis* infection are acute. In untreated animals the disease is progressive. The CSF of animals with *Parelaphostrongylus* infection contains increased concentrations of protein (56 to 157 mg/dL), RBCs (300 to 41,000/µL), and WBCs (17 to 700/µL). The differential cell counts contain a large number of eosinophils (7% to 97%).[2030]

35.57.8 CATTLE

35.57.8.1 Hypoderma Bovis

After hatching, the larvae of *H. bovis* burrow through the skin and migrate along the peripheral nerves to the spinal canal. When the larvae reach the spinal canal, they lie dormant for 2 to 3 months in the epidural fat. Most of the larvae lodge in the lumbosacral part of the spinal cord; very few are found in the cervicothoracic region. If the larvae are killed while lodged in the epidural fat, the host mounts a marked inflammatory response. The swelling and inflammation caused by the dead worms results in spinal cord disease. In clinical practice these signs most often occur by 2 days after administration of a systemic organophosphate grub treatment.[2027,2028] Other drugs that kill *Hypoderma* larvae in the spinal cord could cause a similar problem. In most of North America the grub is located in the epidural space between the months of July and October.

The clinical signs of hypodermiasis include stiffness of the rear limbs, ataxia, paraparesis/paraplegia, hemiparesis/hemiplegia, or tetraparesis/tetraplegia. The conscious proprioceptive responses are greatly altered in the affected limbs. Reflex activity varies, depending on the level of the lesion in the spinal cord.

The CSF changes of hypodermiasis vary. Because of the epidural location of the grub, most affected animals have normal CSF values. If pressure changes induce vascular damage, CSF changes might include mild xanthochromia and slight increases in WBCs and the protein concentration.

35.57.9 Setaria digitata

Infection of the spinal cord of cattle by *S. digitata* has been described in India.[2017]

35.57.10 Diagnosis of Parasitic Infestation of Central Nervous System

Parasitic myeloencephalopathy must be considered in all cases of acute asymmetric disease of the spinal cord, cerebellum, or brainstem. Identification of eosinophils in the CSF may be helpful; however, this pattern is not seen in every neuroparasitic diseases. For example, *Hypoderma* infestations often are extradural, and CSF

changes reflect only increased pressure. The CSF of horses with acute *S. vulgaris* migration could be normal or could show xanthochromia, increased concentrations of RBCs or WBCs, and increased protein concentration.[2009]

35.57.11 Treatment

Although severe reactions often are associated with death of the CNS parasites, administration of parasiticides in conjunction with heavy antiinflammatory therapy is recommended. Such treatment prevents further migration of the parasite yet mitigates the host inflammatory responses.

The recommended treatment for neural *S. vulgaris* infection is either thiabendazole (440 mg/kg PO daily for 2 days) or mebendazole (30 mg/kg daily for 2 days). Horses should also be given a combination of corticosteroids and NSAIDs for 10 days after administration of the parasiticides.

Some experts speculate that ivermectin may be a valuable broad-spectrum treatment for all CNS parasitic infections. The drug has a prolonged plasma half-life after parenteral or oral administration (2.7 days) and may exert an antiparasitic effect for as long as 14 to 21 days after subcutaneous administration.[2031–2033] Although ivermectin diffuses across the blood-brain barrier, the plasma concentrations after oral administration are low, and the drug should be administered parenterally to achieve optimum efficacy. Unfortunately, significant side effects occur (0.92% overall adverse reaction rate) after parenteral administration to horses.[2034,2035] Consequently, until ivermectin is proved to be effective by pharmacologic and clinical studies, alternative parasiticides should be considered for initial treatment of parasitic CNS disease in horses.

35.57.11.1 HYPODERMA BOVIS

Systemic organophosphate insecticides formulated for oral administration or pour-on application have been recommended for eliminating *H. bovis* from the CNS. These one-time formulations include crufomate (75 mg/kg as 13.5% Ruelene), trichlorfon (40 mg/kg PO), famphur* (13.2% 1 fluid ounce per 90 kg body weight, not to exceed total dosage of 4 oz for cattle), ronnel (100 mg/kg PO for cattle or horses), and ivermectin 0.5% solution (1 mL/10 kg). Although ivermectin kills the cattle grub in the subcutaneous tissues, its safety and efficacy in the treatment of clinical neurologic disease are uncertain.

It is important to remember that the treatment of affected animals with any of the systemic parasiticides may aggravate neurologic disturbances through release of toxic factors or the development of local immunologic responses to the dying worms.[2019,2036] Concomitant treatment with corticosteroids (e.g., dexamethasone, 0.1 to 0.25 mg/kg IV every 6 hours) 1 day before and 5 days after treatment is recommended to reduce the inflammation. Dying cattle grubs also release a systemic toxin that lowers blood pressure and causes acute dyspnea and collapse. The systemic toxic effects of the dying grubs can be ameliorated by concomitant administration of phenylbutazone (4 mg/kg IV or PO twice daily in horses; 10 mg/kg IV or PO once every 36 hours in cattle), aspirin (100 mg/kg PO two or three times daily for cattle), or flunixin meglumine (1 to 2.2 mg/kg IV twice daily for horses or cattle). Naproxen (10 mg/kg IV twice daily for horses) may be a useful alternative to phenylbutazone therapy.

Hypoderma infestation can be controlled by prophylactic administration of the pour-on insecticides before worms have migrated into the nervous tissues. The appropriate time for application of the grubicide depends on the time of pupation and the emergence of adults. In most of North America the flies emerge by May, and the larvae reach the nervous tissues by November. Therefore, prophylactic treatment of cattle or horses with

organophosphorus compounds should be completed by August or September in warmer climates and October in colder areas.

* American Cyanimid, Wayne, NJ.

35.57.11.2 PARELAPHOSTRONGYLUS TENUIS

A number of drugs, including levamisole (7 mg/kg PO in a single dose), diethylcarbamazine (40 to 100 mg/kg twice in 72 hours), and thiabendazole (250 to 440 mg/kg PO on 2 consecutive days), may be effective for eliminating *P. tenuis* from the CNS.[2013,2037] Ivermectin has been administered to some affected goats, but only one of three treated animals recovered.[2030] The lack of response to ivermectin was related to its poor distribution in the CNS. Administration of ivermectin to animals before exposure protects them from larva migrans for 7 to 14 days.[2038] All patients treated with anthelmintics should be given corticosteroids and NSAIDs concomitantly.

35.57.11.3 *SETARIA* SPECIES

Administration of a single dose of diethylcarbamazine (80 to 100 mg/kg PO) may be effective against migrating *Setaria* larvae and adults. The drug also has been shown to be effective in preventing infection in sheep and goats when given at 20-day intervals (40 mg/kg PO) during the vector season. The efficacy of diethylcarbamazine in the treatment and prevention of *Setaria* infection in horses is unclear. As with therapy for other parasitic nervous system infections, patients should be given corticosteroids and NSAIDs concomitantly with the parasiticide therapy.

35.58 FIBROCARTILAGINOUS EMBOLIZATION

Fibrocartilaginous embolization has been described in horses, lambs, and a calf.[2039–2044] The clinical signs are those of an acute to peracute onset of myelopathy that usually is asymmetric. Paresis to paralysis of the limbs caudal to the lesion occurs, as does hyperreflexia (if the lesion is above the brachial or lumbosacral intumescences) or hyporeflexia to areflexia (if the lesion is in an intumescence). Differential diagnoses that should be considered include traumatic injuries and, in horses, equine herpesvirus infection. Other types of myelopathy usually have a more gradual onset and less acute course. Lambs may develop diffuse tremors that resemble the truncal ataxia of cerebellar disease. The index of suspicion is increased by ruling out other causes of myelopathy, but definitive diagnosis usually is only made at necropsy. There is no effective treatment for the condition, and affected large animals have not recovered. In dogs, however, in which a similar or identical condition is common, partial to complete recovery over several weeks to months is common and might be anticipated in some milder cases in large animals, particularly when the signs are the upper motor neuron type.[2045,2046]

The emboli are believed to originate from the nucleus pulposus of the intervertebral disks and can be identified histologically using an alcian blue stain.[2042] The exact cause of the embolization and the associated mechanisms are unknown. Pressure changes or lesions associated with degenerative arthropathy might result in herniation of disk material into the marrow cavity of a vertebral body. From there the material is hypothesized to enter the basivertebral veins and pass retrograde along the valveless basivertebral plexus to the spinal veins, where it gains access to the vertebral arterial circuit. The manner in which the material enters the arteries is unknown, but some authors have postulated the presence of arteriovenous shunts in the vertebral vasculature.[2039] Other mechanisms proposed to explain embolization include herniation of nucleus pulposus into persistent or anomalous embryonic

vasculature, into neovasculature formed at the site of a chronically degenerated intervertebral disk, or through the vertebral endplate via Schmorl's nodes into the marrow cavity of the vertebrae and then into the vascular system. Sudden increases in pressure within the disk, such as may occur during exercise or from trauma, may play a role in the formation of emboli. Once the material has embolized, the neurologic signs are related to swelling, infarction, necrosis, and hemorrhage of the neuropil. The emboli occur exclusively in the brainstem, spinal cord, and cerebellum. The CSF of affected animals has been reported to be normal,[2040] but mild pleocytosis and elevations in the protein concentration could be expected in CSF obtained caudal to the lesion in some cases.

35.59 POSTANESTHETIC MYELOPATHY AND ENCEPHALOPATHY

A sudden-onset myelopathy has been described in several horses and in a calf after anesthesia.[2047–2050] Most of the horses were young and in dorsal recumbency during anesthesia. The calf described with a similar syndrome was severely hypotensive during anesthesia. Paraparesis, ataxia, recumbency, or paraplegia occurs immediately after anesthesia or within a few days. Other reported signs include hypalgesia and scoliosis. Lesions occur mainly in the thoracolumbar spinal cord, although the cervical spine may be involved, and consist of malacia predominantly within gray matter (poliomyelomalacia), with severe hemorrhage in the spinal cord parenchyma (hemorrhagic myelomalacia) in some cases.

Rare cases of postanesthetic encephalopathy have been described in horses.[2051,2052] Clinical signs included dementia, pacing and circling, cortical (“central”) blindness, ataxia, hypermetria, and recumbency. The onset of signs ranged from a few hours after recovery to several weeks later. The major pathologic finding in affected horses was cerebrocortical necrosis, particularly in regions of the cortex supplied by terminal arterial branches (“watershed zones”).

Although the pathogenesis of postanesthetic myelopathy is incompletely understood, it likely results from compromise of the vascular supply to the spinal cord caused by hypotension or pressure from the abdominal viscera on the great veins (caudal vena cava, azygous vein) resulting in venous stasis. Similarly, systemic hypoxia, hypovolemia, and hypercapnia may underlie postanesthetic encephalopathy.[2052] Factors suspected to increase the risk of postanesthetic encephalopathy include positioning in dorsal recumbency during anesthesia, multiple anesthesias, endotoxemia, and shock. Differential diagnoses for myelopathy include orthopedic conditions such as limb fractures, spinal fracture, and myopathy secondary to recumbency. Differentials for encephalopathy include numerous metabolic, infectious, and toxic disorders. Prognosis for recovery in both conditions is poor. The risk of these complications probably can be reduced by supporting adequate blood pressure and ventilation in patients under anesthesia and avoiding placing patients in dorsal recumbency whenever possible.

35.60 OCCIPITOATLANTOAXIAL MALFORMATION

Occipitoatlantoaxial malformation appears to consist of a spectrum of cervical spinal abnormalities rather than a single specific anatomic defect.[2053] It occurs in cattle, sheep, goats, and horses.[2054–2056] At least five different types of defect have been reported in horses, as follows[2057–2064]: 1083 1084

1 A heritable condition in Arabians characterized by symmetric atlantooccipital fusion, atlantalization of the axis, and hypoplasia of the atlantal wings.[2058,2062,2065] A similar disorder has been reported in an Arabian-cross colt.[2066]

2 A nonfamilial disease of quarter horses with spinal lesions similar to the lesions in Arabians.[2067,2068]

3 Asymmetric malformations of the occipitoatlantoaxial area in Morgan horses and standardbred foals.[2053]

4 Atlantal duplication in Arabian and Arabian crossbred horses.[2069,2070]

5 Asymmetric occipitalization of the atlas and symmetric atlantalization of the axis.

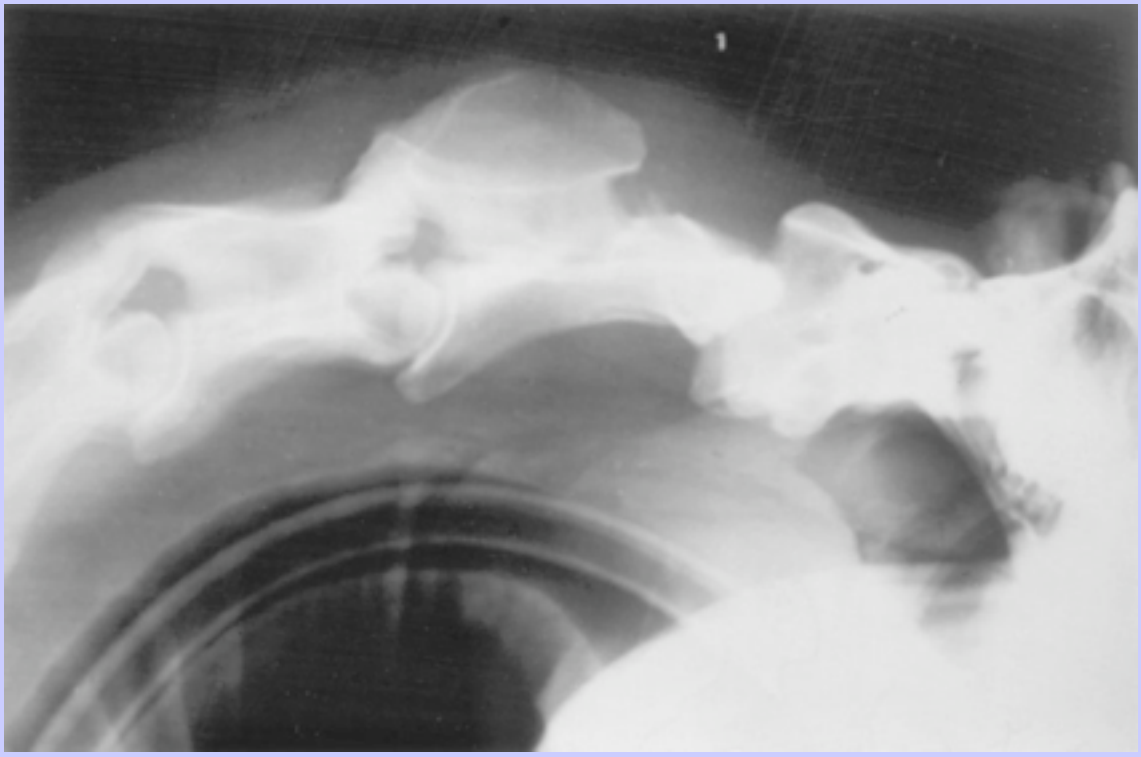
Macroscopic pathologic lesions common to the five forms include loss or flattening of the occipital condyles, asymmetric flattening of the articular surfaces of the axis, and shortened dens. The pathogenesis of the vertebral defects is unknown, but the disease has been shown to be heritable in the Arabian horse.[2071]

The clinical signs vary considerably and range from normal neurologic function with or without torticollis to brainstem compression, sudden unexpected death, and stillbirth.[2053] In typical cases, signs of tetraplegia or tetraparesis begin at or shortly after birth and progress at a variable rate. Foals may become suddenly tetraplegic, appear to stabilize for several days, but then die suddenly.[2062] In rare cases, horses may not show nervous system signs until 3 years of age.[2061]

The signs are symmetric in most affected animals and include conscious proprioceptive deficits, tetraplegia, hyperreflexia, and hypertonia. Some affected animals may show a reluctance to move the neck and head and resist vigorously when the proximal cervical area is passively flexed. A clicking, creaking, or crepitation may be palpated over the cervical spine when the head is moved.[2053,2057] Animals with asymmetric bone lesions often show torticollis, whereas patients with symmetric lesions hold their heads in extension and frequently display the "weather vane" attitude. Neurologic deficits may not be seen despite moderate torticollis.

The bone lesions are readily apparent on radiographic examination (Figs. 35-38 and 35-39), and computed tomography (CT) can further elucidate the anatomic abnormalities.[2067] Affected animals may show subluxation of the atlantoaxial joint, ventral displacement of C2 in relation to C1, nonunited ossification center of the dens, shortened or elongated dens, shortened transverse process of the atlas, fusion of C1 with the occipital condyles, atlantal duplication, and deviation of the basilar bone.[2072] In sheep, additional malformations of the cervical vertebrae have been seen concomitantly.

Fig. 35-38 Lateral radiographic view of a 2-month-old foal with occipitoatlantoaxial malformation. The atlas is occipitalized, and the axis is subluxated dorsally. The odontoid process of the dens is hypoplastic and is not anchored to the floor of the atlas. Courtesy Dr. W.D. Wilson.



Some suggest that treatment could include surgical fusion of the atlantoaxial joints, with or without a laminectomy.[2058,2061,2073–2075] Laminectomy alone has been used to alleviate spinal cord compression and clinical signs caused by occipitoatlantoaxial malformation.[2076] However, long-term results of surgical intervention have been poor, with neurologic deficits persisting. Closed reduction of the luxated atlantoaxial joint has been similarly unsatisfactory.[2067,2077] Arabian horses should not be treated because of the hereditary nature of the disease in that breed.

35.61 SYSTEMIC NEUROAXONAL DYSTROPHY

Systemic neuroaxonal dystrophy is seen in purebred Suffolk sheep.[2078] The animals are born normal but show a hindlimb ataxia beginning at 1 to 5 months of age. The disease is progressive, and eventually the animals become recumbent and either die or are euthanized after 8 to 10 weeks. Pedigree analyses have indicated that an autosomal recessive trait may be responsible for the condition. The pathology of this disease is characterized by numerous focal axonal swellings in gray matter and adjacent white matter, particularly in areas of the spinal cord and brainstem involved in conscious proprioception (dorsal and intermediate horn gray matter in spinal cord, various

nuclei in medulla and caudal midbrain). A condition that is clinically and pathologically similar to systemic neuroaxonal dystrophy has been described in 4- to 7-month-old Merino lambs.[2079]

35.62 WEAVER SYNDROME (BOVINE PROGRESSIVE DEGENERATIVE MYELOENCEPHALOPATHY)

Weaver syndrome is a progressive hereditary CNS disease of 5- to 10-month-old Brown Swiss and Angler cattle.[2080,2081] The disease has been reported in the United States, Canada, Denmark, and Switzerland. The incidence of weaver syndrome in some countries may be as high as 563 per 100,000 registered Brown Swiss cattle.[2082,2083] The disease affects both genders, but males are affected more often than females.[2082]

Fig. 35-39 Dorsoventral myelogram of a foal with occipitoatlantoaxial malformation showing spinal compression and attenuation of the contrast column at the C1-C2 vertebral junction *(arrow)*.

Affected animals develop clinical signs between 5 and 8 months of age. The animals are easily pushed around by herdmates and show marked proprioceptive deficits when forced to move. The clinical signs worsen until the animals become recumbent by 18 to 36 months of age.[2080,2084,2085] The pelvic limbs are most severely affected. Specific signs include weakness, ataxia, conscious proprioceptive deficits (circumduction, crossing over, interference, knuckling), muscle tremors, and recumbency. In early stages, attempts to move rapidly may result in cessation of movement of gait in the hindlimbs while the animal continues to pull with the forelimbs, causing the hindlimbs to be pulled too far caudally. Some animals may show varying degrees of hypermetria ("goose stepping" gait) in the limbs. The spinal reflexes and cranial nerve function are normal. Anestrus in females and aspermatogenesis of affected bulls have been described.[2085] The disease is progressive and leads to irreversible recumbency. The sensory nerve conduction velocity is reduced in affected calves, but motor nerve conduction velocity is normal. Electromyograms and electroencephalograms are normal in affected calves.[2086] The CSF of affected cattle may show an increased concentration of protein (0 to 127 mg/dL) and creatine phosphokinase (2 to 89 mg/dL).[2087]

Except for muscular atrophy of the pelvic limbs (in long-standing cases), the small ovaries, and hypoplastic testicles, macroscopic lesions are not seen.[2082,2088,2089] Although severe muscular changes are not observed, ultrastructural studies of muscle from affected cattle support the hypothesis that myopathic changes are a significant feature of bovine myeloencephalopathy.[2090,2091] The primary microscopic abnormalities include degeneration of the rubrospinal spinocerebellar tracts, particularly in the ventral funiculi of the thoracic spinal cord. The lesions include axonal degeneration, vacuolation of the white matter, spheroids, phagocytosis of myelin debris, gliosis, and status spongiosus.[2082] Axonal swellings have been observed in the brainstem nuclei and medulla oblongata. An ultrastructural study has shown a reduction of the height of the paramembranous densities of the synaptic junctions of affected cattle,[2092] indicating impairment of transmitter releases, dysfunction of the synaptic endplates, or losses of specific cell populations from the motor cortex. Other ultrastructural changes include axonal swelling and vesiculation, swelling of the mitochondria of the Schwann cells, and membrane-bound vesicles.[2085,2093] Cerebellar lesions include degeneration and loss of Purkinje's cells and swelling of Purkinje cell axons.[2088]

The disease is thought to be transmitted by a simple autosomal recessive trait. Apparent association between the weaver condition and genetic predisposition for high milk yield would favor retention of weaver carriers in situations of intense genetic pressure for production.[2094] A genetic test is available for this disease.[2095] Carrier bulls identified by the American Brown Swiss registry are designated by the suffix "W" as an integral part of their registry name.[2096]

35.63 PROGRESSIVE SPINAL MYELINOPATHY OF BEEF CATTLE

Spinal myelinopathy of beef cattle has been reported in Australia.[2097] The condition occurs mainly in animals of the Murray Grey breed and is inherited in an autosomal recessive manner.[2098] Most of the affected animals are unable to stand at birth. Less severely affected calves usually exhibit severe conscious proprioceptive defects. The muscular tone of the hindlimbs is increased. The condition is progressive, and affected animals die or are euthanized by 12 months of age.

The pathologic changes are restricted to the spinal cord white matter, with swollen axons, dilated myelin sheath, wallerian degeneration, and ballooning of the axonal sheaths. There is mild chromatolysis. The animals have normal hepatic copper concentrations, indicating that the condition is not related to enzootic ataxia.[2097]

35.64 BOVINE SPINAL MUSCULAR ATROPHY

Bovine spinal muscular atrophy (SMA) is a heritable disorder of Brown Swiss cattle, certain breeds derived from the Brown Swiss (e.g., Braunvieh, Red Swiss), and Holstein-Friesians.[2099–2103] Most affected calves appear normal immediately after birth but within a few weeks develop severe weakness and rapidly progressive muscle atrophy, particularly affecting proximal musculature. Calves deteriorate rapidly; most become recumbent and develop bronchopneumonia. SMA is characterized pathologically by degeneration of motor neurons in the ventral horn of the spinal cord gray matter (equivalent to human anterior horn cells). Pathology is most severe in the brachial and lumbosacral plexuses but occurs throughout the spinal cord. Abnormalities include neuronal loss, swelling and accumulation of phosphorylated neurofilaments, and neuronophagia.[2104] These findings suggest that neuronal degeneration in SMA is a consequence of necrosis rather than apoptosis.[2102,2104] Sensory neurons are unimpaired.[2099,2105] The SMA-determining gene has recently been mapped to chromosome 24 in Brown Swiss cattle, similar to the equivalent gene in humans.[2106,2107] Bovine SMA is inherited as an autosomal recessive trait.[2099] Although this condition resembles weaver syndrome, the two diseases can be differentiated clinically. Signs of spinal muscular atrophy usually are first seen between 2 and 5 weeks of age. Calves with weaver syndrome first show signs at 5 months of age. The degree of muscular wastage is much greater in calves with spinal muscular atrophy than with weaver syndrome.[2108] SMA also must be distinguished from the dysmyelination described in Braunvieh and Brown Swiss–Braunvieh calves (see next section).

1085 1086

35.65 SPINAL DYSMYELINATION OF BRAUNVIEH AND BRAUNVIEH-CROSS CALVES

A congenital spinal condition characterized by dysmyelination of the dorsal tracts of the spinal cord has been described in Braunvieh–Brown Swiss crossbred calves.[2109] Test matings have shown that the disease is inherited in an autosomal recessive manner.[2110] Calves are recumbent from birth. They have a coarse tremor of the head, neck, and body when stimulated and generalized muscular atrophy. Necropsy findings included deficient myelin production and demyelination of the dorsal sensory tracts of the spinal cord. The neurons of these calves are normal, which differentiates the condition from weaver syndrome and spinal muscular atrophy. A similar condition was described in purebred Braunvieh calves; recumbency from birth, opisthotonos, and muscular spasticity with increased reflexes were present in affected calves.[2111] Bilaterally symmetric reduction of myelin was found in the spinal cord.

35.66 MYELOPATHY IN HOLSTEIN-GIR CALVES

A single report describes a myelopathy in Holstein-Gir calves in Brazil.[2112] Calves were normal at birth but developed quadriparesis and ataxia at about 3 months of age, becoming recumbent within 1 to 2 weeks after onset of signs. All died from respiratory complications within a few weeks. Nervous system lesions were confined to the spinal cord in all except one calf examined; findings were consistent with a dying-back neuropathy. Lesions were broadly symmetric bilaterally and not limited to any specific tracts within the cord. In one calf, small glial nodules were found in the basal nuclei and medulla. Both male and female calves were affected, and all were offspring of a single Holstein bull, supporting a genetic but not sex-linked basis for this disorder.

35.67 NEUROPATHY, MYOPATHY, AND GLOMERULOPATHY OF GELBVIEH CATTLE

A disorder affecting peripheral nerves, spinal cord, kidneys, and muscles has been described in a small number of Gelbvieh calves.[2113,2114] Animals present with progressive ataxia, stiffness, and weakness at a few weeks of age to slightly over 1 year old. Signs may start in the rear limbs but progress over weeks to months to affect all limbs. Animals may become recumbent but remain bright, with a good appetite. Muscle atrophy is frequently observed, as are flaccid paresis, hyporeflexia, and decreased anal tone.[2114] Hypalgesia to analgesia may be present in affected limbs. Signs of cranial nerve dysfunction are rare. Proteinuria is the most consistent abnormality of clinical chemistry, whereas other changes, such as neutrophilia and elevated serum creatine kinase, are variable and may relate to secondary problems (e.g., muscle damage when recumbent). Histologic alterations include degenerative changes in peripheral nerves and spinal cord (particularly dorsal columns), renal lesions described as "interstitial nephritis" or "glomerulopathy," and variable myopathic changes (e.g., necrosis, fibrosis, atrophy). Vascular lesions also have been described.[2113] Controversy surrounds the relative severity and importance of neuropathy, myelopathy, and myopathy, but all agree that all these tissues are involved and that renal lesions are prominent. Studies of potential toxicities or nutritional deficiencies within affected herds tend not to support these etiologies, but rather suggest that this is a heritable disorder. The exact mechanism of inheritance and the molecular basis for this disease have not been elucidated. No treatment has been described, and the prognosis appears to be poor. Prevention likely would involve changes in breeding management.

35.68 PROGRESSIVE ATAXIA OF CHAROLAIS CALVES

Progressive ataxia occurs in purebred and crossbred Charolais calves of both genders between 6 and 36 months of age.[2115–2120] The condition has a worldwide distribution. Affected calves develop posterior paresis and become recumbent by approximately 2 years of age. The disease is thought to be caused by a recessive genetic defect. Preliminary studies to locate the defect in the gene coding for myelin basic protein have been reported.[2121] The clinical signs begin with posterior ataxia and end in lateral recumbency. Other neurologic signs of progressive ataxia include stiffness of the neck, aggressiveness, dragging of the rear toes, stumbling, and loss of conscious proprioception (abduction, knuckling, circumduction, abnormal leg placement at rest).[2122] In the initial stages of the disease, the gait deficits worsen with exercise and improve after a period of rest. Muscular tremors or a jerking movement of the limbs and tail may be seen when the affected animal attempts to rise.[2117,2123] Some animals may be found down acutely and primarily show signs of central vestibular disturbance.[2122] Head bobbing may be observed, but affected animals have no other signs of brain involvement. Difficulty in assuming and maintaining a urination posture and prolonged pulsatile micturition are characteristic abnormalities in affected animals.[2115,2119,2124] The major pathologic lesion is eosinophilic plaques in the white matter of the brain. Plaques also extend into the white matter of the cerebellar folia and peduncles. Ultrastructural changes include hypertrophy of oligodendrocytes and dysmyelination.[2125] These lesions, which have been characterized as an oligodendrogial dysplasia, are almost unique to this particular disease of Charolais cattle, although similar pathology has recently been described in dogs.[2126]

35.69 SPASTIC PARESIS (ELSO HEEL)

Spastic paresis is characterized by marked asymmetric spasticity and hypertonia of the rear limbs. The etiology is uncertain; it may be genetic. Breeds in which the condition has been recognized include the Holstein, Brahman, Angus, shorthorn, Charolais, Simmental, Red Danish, crossbred shorthorn, Gelbvieh, Ayrshire, polled Hereford,

Hungarian red spotted, Kankrej, Belgian blue, and other rare European breeds.[2127–2139] The clinical signs of this condition are clinically similar to inherited periodic spasticity (see next section), except that spastic paresis is seen in young animals (onset at 3 weeks to 1 year of age) and occurs at all times when the animal stands.[2127–2130] In comparison, inherited periodic spasticity occurs in adults in episodic fashion, with normal gait between episodes. Spastic paresis has been recognized in pygmy goats.[2140]

1086

1087

35.69.1 Clinical Signs

Spastic paresis is characterized by intermittently increased extensor tonus in the pelvic limb as the animal attempts to walk.[2127,2131,2136,2141] The gastrocnemius and superficial digital extensor muscles are spastically contracted in all calves, whereas the biceps femoris, adductor, quadriceps, semitendinosus, and semimembranosus muscles are less often affected.[2128,2131,2141,2142] The extensor tone is normal when the calf is recumbent and relaxed but becomes excessive when the animal stands and attempts to bear weight. The excessive extensor motor activity results in an inability to flex the hock during protraction of the pelvic limb. To prevent the toes from dragging, the limb is circumducted, resulting in a pendulum-like motion.[2142] At rest the limb is held stiffly abducted and is repeatedly circumducted. The foot is held off the ground, and the gastrocnemius muscles appear to be underdeveloped. The tail is elevated from the ischiorectal fossa as the animal attempts to move. Eventually there is atrophy of the hindquarters. The spasticity is progressive, and affected animals experience difficulty rising and grazing. If untreated, the animals are stunted and usually are culled.

The excessive pull of the extensor tendons produces radiographically detectable changes in the bones of the hock, including osteoporosis, lipping of the dorsal aspect of the tibial epiphysis, plantar displacement of the proximal part of the tibial diaphysis and epiphysis, and excessive straightening of the tuber calcis.[2127,2128,2143]

The etiology and pathogenesis of spastic paresis are unknown. Some investigators have documented the presence of subtle demyelinating lesions of the red nucleus but were unclear about the contribution of these changes to the clinical syndrome.[2132,2134] Changes observed in affected calves include nonsuppurative encephalitis and reduced concentrations of dopamine and 5-homovanillic acid in the cerebrospinal fluid.[2144] There are no histologic or biochemical alterations of the myofibrils.[2145] Neuropharmacologic studies have indicated that the disease may be related to overstimulation of the gamma motoneurons of the spinal cord.[2146] A genetic basis for the disease has been postulated because affected offspring tend to have a common paternity[2127,2130,2132]; however, breeding experiments and progeny evaluation of cattle have not demonstrated heritability. The condition has been seen in female calves only, in one case, and occurred in a single year; calves with the same parentage born in previous and subsequent years were not affected, and calves in the same environment but with different parentage were unaffected.[2139] This suggests that a conjunction of environmental and genetic factors may determine disease pathogenesis. Consequently, some authors do not recommend culling a bull merely because an offspring has developed the condition,[2147] whereas others disagree with this recommendation.[2148]

35.69.2 Treatment

Surgical techniques for correction of the spasticity include sectioning of the spinal afferents at segments L4 through L6, neurectomy of the tibial nerve rootlets supplying the medial and lateral heads of the gastrocnemius

muscle, and superficial digital flexor tenotomy proximal to the tuber calcis.[2129,2141,2149–2151] The tenotomy procedure is performed by incising proximal to the tuber calcis and transecting the superficial head of the gastrocnemius tendon completely (this tendon twists around the superficial digital flexor tendon from medial to lateral, coursing distally) and partly nicking the superficial digital flexor tendon.[2150,2152]

To perform a tibial neurectomy, an incision is made in the groove separating the heads of the biceps femoris. The tibial nerve is identified as the more caudal of the branches off the ischiatic nerve. Some surgeons have recommended a concomitant sectioning of the caudal cutaneous sural nerve.

Success rates of 82% for the neurectomy technique and 40% for the tenotomy procedure have been reported.[2149,2153] Although recurrences may be common, some authors found high rates of sustained improvement over several months with the neurectomy technique.[2149] Results are poorer when animals under 2 months of age are treated.

Despite the reported success of these procedures, these treatments are not routinely performed in most countries because of the possible heritability of the condition and the need for specialized instruments and general anesthesia. Administration of lithium gluconate (4 g/100 kg IM daily for 10 to 30 days) is reportedly efficacious when used to treat calves in the early stages of spastic paresis.[2135]

35.70 INHERITED PERIODIC SPASTICITY (CRAMPY SYNDROME; STRETCHES; BARN CRAMPS; KRAMPFIGKEIT)

Inherited periodic spasticity is seen frequently in Holstein, Ayrshire, Jersey, Brown Swiss, and Guernsey cattle of either gender.[2154] Beef cattle are rarely affected. The condition is thought to be transmitted by a single autosomal recessive factor.[2155] Affected cattle are normal until they reach 3 to 7 years of age, when they develop marked muscular spasms of the hip and upper limb.[2154] An earlier onset was reported in a Hereford bull.[2156] The disease is mild for the first 2 to 3 years but progressively worsens over time. Eventually, affected animals are culled early because of weight loss or chronic foot problems. Specific pathologic changes are absent at necropsy.[2157]

35.70.1 Clinical Signs

During the attack the leg may be held spastically in flexion, but more often it is held in rigid extension. The attacks are episodic, which differentiates them from the spasms of spastic paresis. The two diseases are otherwise similar in appearance. Each spasm is accompanied by kyphosis, which initially lasts 15 to 30 seconds and often is terminated by a fine tremor in the hindquarters or the digit. The intensity and duration of the spasms progressively increase over time. Both hindlimbs are affected. During a spasm the animal usually extends or flexes only one leg at a time. Some animals with advanced disease arch the neck and back dorsally and lift the contralateral forelimb during an attack.[2154] At first the signs appear to typify a response to a painful focus, and affected animals may be misdiagnosed as having laminitis, colic, or peritonitis. Gait and proprioceptive responses appear normal.

35.70.2 Treatment

There is no specific treatment for periodic spasticity, although mephenesin has been recommended, at a total 3-day dosage of 100 to 120 mg/kg orally. Although the pharmacologic effect of mephenesin lasts only 6 to 8

hours, severe symptoms were reportedly reduced for as long as several months after a single course of therapy.[2158] Methocarbamol also has been recommended, but reports of efficacy are anecdotal only.

35.71 DODDLER SYNDROME (HEREDITARY LETHAL SPASMS)

Doddler syndrome is a rare congenital lethal trait of Jersey cattle.[2159] The calves are down but appear bright and alert and usually are able to suckle. When stimulated, they develop severe intermittent spasms of the head and neck and convulsions. The animals can stand with assistance but are very ataxic and fall easily. They have a severe head tremor when forced to stand. The signs improve when the animal is allowed to rest but worsen again with restimulation.[2160] Calcification of multiple neurons and small vessels in the brainstem and cerebellum is observed at necropsy. The condition probably is inherited as a lethal autosomal recessive trait.

1087 1088

35.72 CONGENITAL VERTEBRAL ANOMALIES (SPINA BIFIDA; BUTTERFLY VERTEBRAE; HEMIVERTEBRAE; ARNOLD-CHIARI SYNDROME)

A large number of spinal deformities have been reported in domestic livestock, including the following:

- *Spina bifida*. Failure of closure of a vertebral neural arch; spina bifida usually occurs concomitantly with one of the forms of myelodysplasia.[2161,2162]
- *Spina bifida cystica*. Spina bifida associated with a cerebrospinal fluid cyst at the site of the bony defect.
- *Hemivertebra*. A unilaterally incomplete vertebral segment; spina bifida and hemivertebrae have been described in calves, and spina bifida also has been reported in sheep and foals.[2161–2170]
- *Arnold-Chiari syndrome*. A complex disorder that occurs in lambs and calves[2171] and is characterized by a number of pathologic changes, including herniation of cerebellar tissue through the foramen magnum, caudal overgrowth and displacement of the brainstem, internal hydrocephalus, polymicrogyria of the cerebral cortex, malformation of the base of the skull, and enlargement of the foramen magnum. The strong correlation between the occurrence of spina bifida and Arnold-Chiari syndrome of calves indicates that the pathogenesis of the two conditions may be interrelated.[2161,2171]

Animals with spina bifida may be asymptomatic or may show paraparesis and paraplegia or tetraparesis and tetraplegia. If the spina bifida is associated with syringomyelia, the calves may have a peculiar “rabbit hopping” gait. The clinical signs often are present at birth or develop in the first 2 postnatal months.[2168,2172] Kyphoscoliosis and abnormalities of the rib cage may be seen at birth in some animals.[2168] The skin over the abnormal vertebrae may be smooth and hairless. When examined microscopically, this tissue resembles meninges or ependyma.[2162,2163]

Spina bifida and hemivertebrae are easily diagnosed by examination of plain radiographs. The specific site of central nervous system stenosis can be detected by performing a myelogram. The etiology of spina bifida is unknown, but some suggest that it may have either genetic[2163–2165] or toxic etiologies.[2173,2174]

Arthrogryposis occurs secondary to the spinal cord changes. Spina bifida and myelodysplasias are not the only causes of arthrogryposis, however, and clinicians should attempt to differentiate between these and other diseases that interfere in utero with motor neuron development in the spinal cord. Nongenetic arthrogrypotic conditions of

cattle include perosomus elumbis, hydranencephaly, manganese deficiency, and ingestion of lupines or *Nicotiana glauca* (40 to 60 days of gestation).[2175–2179]

(See also Chapters 51 and 52.)

35.73 MYELODYSPLASIAS (SYRINGOMYELIA; SPINAL DYSRAPHISM; HYDROMYELIA)

The following types of myelodysplasia occur in livestock[2180–2182]:

1. *Spinal dysraphism*. A general term denoting arrested development of the spinal cord before complete differentiation of gray and white matter; the areas of agenesis form longitudinal cystic structures instead of differentiated nervous tissue.
2. *Syringomyelia*. Longitudinal canalicular cavitations of the spinal cord.
3. *Hydromyelia*. Abnormal dilation of the central canal.
4. *Diastematomyelia*. Duplication of the gray matter at one or more segments.
5. *Rachischisis*. Complete failure to close the neural tube; the central canal remains open and communicates with the integument.
6. *Meningocele*. Herniation of the dura mater through a spinal column defect.
7. *Meningomyelocele*. Herniation of the meninges through a spinal column defect and a concomitant myelodysplasia.

Myelodysplasias are most often seen in Charolais calves, in which the condition is associated with palatoschisis and arthrogryposis.[2180,2183] The condition has also been recognized in 5-month-old thoroughbred foals and an Arabian foal.[2184,2185]

The neurologic deficits of myelodysplasia are difficult to differentiate from other spinal diseases unless the disorder is accompanied by spina bifida. Clinical recognition of myelodysplasia usually is based on the historical findings of paraplegia in a newborn calf without radiographic evidence of spinal fractures and with no myelographic evidence of spinal cord compression.

35.74 COYOTILLO POISONING (TULLIDORA TOXICITY, BUCKTHORN FRUIT POISONING)

Ingestion of the fruit of the coyotillo plant, *Karwinskia humboldtiana,* by domestic animals produces a stiff stilted gait, hypotonia, and hyperreflexia to areflexia.[2186,2187] The condition occurs in the southwestern United States. The neurotoxin identified in and purified from the plant is called “tullidora” toxin, after another name for the plant itself.[2188] Goats are susceptible to the effects of the intoxication. Daily doses of the fresh plant amounting to 0.04% to 0.05% of the body weight are sufficient to produce neurologic signs by 60 days. The intoxication results in a peripheral polyneuropathy characterized by degenerative changes in both axons and myelin.[2188,2189] Higher dosages may result in neuroaxonal dystrophy characterized by axonal swelling and gliosis. Experimental studies in small animals have revealed that the plant toxin exerts effects both on the Schwann cell and peripheral motor neurons, but not on sensory neurons.[2190] It induces a reversible inflammatory polyneuropathy with segmental demyelination and also decreases fast axonal transport.[2191,2192]

35.75 CYCAD PALM POISONING (*ZAMIA*PARALYSIS)

Ingestion of the palm cycad *Cycas circinalis* L., *Bowenia serrulata, Macrozamia lucida,* and *Cycas media* is associated with the development of posterior paresis in cattle and sheep.[2193–2195] The condition is seen exclusively in the tropics. The toxic principles of the cycad palm are glycosides and methylazoxymethanol (aglycone). The clinical signs include curvature of the spine, elevation of the tailhead, paraparesis, and paraplegia. The anal sphincter and tail tone are normal. Cattle develop ataxia by 50 days after feeding of the plant (3.9 kg wet weight total intake). The cerebrospinal fluid of affected cattle is normal. The pathologic lesions include demyelination, spheroids, and cavitation of the spinal cord white matter. Changes relating to hepatic disease have also been reported.[2196] These lesions included coagulative centrilobular hepatic necrosis, icterus, and petechial hemorrhages on the serous surfaces. Poisoning by *Macrozamia reidlei* can cause death from hepatic failure without signs of neurologic disease.[2197]

1088 1089

35.76 ACQUIRED TORTICOLLIS

Primary acquired torticollis with or without neurologic disease occurs in all species of domestic livestock. Causes include fracture or subluxation of the cervical vertebrae, basilar skull fractures, dystrophic muscle degeneration, unilateral cicatricial muscular contracture from injections, lupinosis, traumatic rupture of the cervical muscles, hydranencephaly, asymmetric neurodegeneration, and congenital vertebral deformity.[2198–2202] Calves with torticollis have a deviated head and neck. One study hypothesized that physical constraint of late in utero development by narrow tips of uterine horns caused acquired torticollis and a variety of other deformities, such as head scoliosis and limb malformations, in more than 200 foals.[2203] Draft horses may be predisposed to this problem, which frequently results in severe dystocia in horses. Provided the spinal cord is intact, no neurologic deficits result.

Treatment of traumatic torticollis should be directed at reducing the edema, relieving pain, and immobilizing the damaged structures. Muscular tears may be treated by incorporating the head, neck, and proximal thorax in a fiberglass cast. Ancillary supportive treatment may include dexamethasone (0.04 to 0.08 mg/kg daily for 2 to 3 days), methocarbamol (8 mg/kg IV daily for 5 days), and NSAIDs (e.g., phenylbutazone PO or IV or flunixin meglumine IV for 3 to 5 days after injury). A method of surgical correction of cervical muscle contractures using a muscle-splitting procedure has been described[2204]; however, this seems unnecessary because most animals recover with only medical treatment. When torticollis is the cause of equine dystocia, delivery of the foal by cesarean section often is followed by rapid and complete anatomic and functional recovery.[2203]

35.77 TETANUS (LOCKJAW)

35.77.1 Definition and Etiology

Tetanus is characterized by muscular rigidity and death from respiratory arrest or convulsions. The disease is caused by the exotoxins produced by the anaerobic, spore-forming, gram-positive bacterium *Clostridium tetani*. Tetanus has a worldwide distribution, and all species of domestic livestock are susceptible. The bacterium is typically isolated from the bowel contents of herbivores, but fecal contamination is considered to be only partly responsible for soil contamination.[2205] The agent also can be found in dirt with no documented contact with domestic livestock. This indicates that *C. tetani* should be considered a primary soil contaminant. Tetanus

usually is a disease of individual animals; however, herd outbreaks of tetanus after tail docking or castration have been described.[2206,2207] During outbreaks of tetanus, *C. tetani* can be isolated from the feces of a large proportion of the cattle, indicating that in some cases the disease may be caused by proliferation of *C. tetani* in the patient's gastrointestinal tract.[2206,2207]

35.77.2 Clinical Signs

The incubation period of tetanus varies and depends on the size of the wound, the redox potential in the contaminated tissue, the number of bacteria inoculated, and the host's antitoxin titer. In most susceptible animals the signs occur from 2 weeks to 1 month after the bacterial inoculation. During the first 24 hours, horses may develop intractable colic, and ruminants may bloat.[2208] The first signs in some animals may be a vague stiffness and lameness of the infected limb, which are related to a local effect of the absorbed toxin (localized tetanus). By 24 hours, generalized spasticity usually is evident. Affected animals display a stiff gait and an extended head posture.[2209] The hypertonia is most evident in the antigravity muscles. Thus the limbs are held in a characteristic posture that resembles the legs of a sawhorse (sawhorse stance). The lips are retracted toward the poll, and the ears are pulled slightly down and caudal. The tail is elevated from the ischiorectal fossa. There is excessive muscle tone of all facial musculature. The jaws are clamped tightly shut (trismus), and the legs are held rigidly extended.

Muscular spasms can be elicited by auditory, ocular, or tactile stimulation. The limbs and head are very resistant to passive flexion. Retraction of the eye and a rapid flashing of the third eyelid across the cornea occurs after a menacing gesture or a slap over the neck.[2208,2210] This sign is more consistently observed in horses than in ruminants. Aspiration pneumonia may develop as a result of impaired deglutition. Severely affected animals become recumbent and lie on their side with the head and legs in full extension and the ears held almost parallel to the thoracic spinal cord (Fig. 35-40). Progression of the disease is associated with increased tonic muscular activity, which results in pyrexia in all species and profuse sweating in horses.[2207,2211] Frothy saliva accumulates at the commissures of the lips because the animals are unable to swallow, and respiratory incursions whip the mucinous saliva into a foam. The respiratory muscles (diaphragm and intercostals) are affected, and the animals develop hypoxia. Ventrolateral strabismus and dilated, fixed pupils may occur in advanced tetanus of cattle. Animals die while in a terminal convulsion. Death is attributable to hypoxemia and heart failure secondary to systemic hypertension and aspiration pneumonia. Survivors begin to show some improvement after 2 weeks, but the clinical signs may persist for as long as 1 month, and lameness may be permanent.

35.77.3 Clinical Pathology

There are no reliable clinicopathologic tests for confirmation of a diagnosis of tetanus. Attempts should be made to culture *C. tetani* from the suspected site of entry.

35.77.4 Pathophysiology

In horses, puncture wounds of the foot or the soft tissues are the most frequent sites of infection, whereas dairy cattle are infected most frequently through the uterus. Other sites for growth of *C. tetani* include lesions induced by elastrator bands, tail docking, dehorning, bull rings, or infected umbilical stalks.[2212] Proliferation of *C. tetani* in the forestomachs of normal cattle may produce sufficient concentrations of toxin to result in clinical

signs.[2213,2214] Outbreaks of tetanus have been correlated with ingestion of millet. This diet has been postulated to promote the growth of *C. tetani* in the large bowel[2215] and probably accounts for the lack of visible wounds in some animals affected with tetanus.[2206,2210]

Fig. 35-40 Characteristic appearance of tetanus in a lamb. This condition developed subsequent to application of an elastrator band to the scrotum.

When inoculated into the anaerobic site, *C. tetani* spores germinate into the vegetative form. Factors that enhance the sporulation and growth of *C. tetani* include necrotic tissue, pus, concomitant bacterial infection, and foreign bodies. Spores inoculated into the tissues are highly resistant to normal host defenses and may remain dormant for months or years before developing into the vegetative state. The production of the tetanus toxins occurs at the end of the logarithmic growth phase of the vegetative form and is governed by a plasmid-associated gene.[2216,2217] The bacterium produces at least three toxic proteins: tetanospasmin, tetanolysin, and a nonspasmogenic toxin. Tetanolysin promotes the spread of the infection by increasing the amount of local tissue necrosis.[2211]

Tetanospasmin is a lipoprotein exotoxin that diffuses from the site of production into the vascular system, where it is distributed hematogenously to the presynaptic part of the motor endplates. Once bound to the nerves, the toxin is internalized and transported to the central nervous system along the axons of the alpha motoneurons through the membrane-bound smooth endoplasmic reticulum.[2209,2218,2219] After reaching the ventral horn of

the spinal cord, the toxin crosses the synaptic cleft to presynaptic inhibitory interneurons (Renshaw cells) in the intermediate gray column.[2220] Tetanospasmin probably inhibits the release of glycine and γ-aminobutyric acid (GABA) from the Renshaw cells, resulting in disinhibition of the gamma motoneurons. The inhibition of these cells results in hypertonia and muscular spasms.

The *nonspasmogenic toxin* is thought to produce overstimulation of the sympathetic nervous system. Systemic hypertension seen in tetanus can be related to excessive catecholamine production by the adrenal medulla. Other physiologic changes identified in humans and laboratory animals include increased plasma cortisol concentrations and neuromuscular blockade. Whether these changes are caused by the effects of the toxin or these are secondary changes occurring in response to a painful and life-threatening problem is unclear. There are no characteristic postmortem lesions associated with tetanus.

35.77.4.1

Treatment

The six general medical principles for treating tetanus in large animals are as follows:

1 Provide muscular relaxation.

2 Ensure good footing.

3 Eliminate the infection.

4 Neutralize the unbound toxin.

5 Maintain hydration and nutritional status.

6 Establish active antitoxic immunity.

35.77.4.1.1

Provide Muscular Relaxation

The patient should be sedated and placed in a quiet, darkened stall. Drugs are administered that may reduce the muscular spasms. These include promazine (0.5 to 1 mg/kg IV) or acetylpromazine (0.05 to 0.1 mg/kg IV) given at 4- to 6-hour intervals. Predictable muscular relaxation may be obtained inexpensively by concomitant IV administration of acetylpromazine (0.06 mg/kg) and 5% sodium pentobarbital (2 to 4 mL/50 kg). An IV catheter may be placed to minimize treatment-associated stimulation. Mephenesin (10 to 20 mg/kg IV three times daily) and guaifenesin have also been recommended. These drugs interfere with the internuncial neurons of the spinal cord that participate in reflex muscle activities. They do not have a high therapeutic efficacy for tetanus. Diazepam (0.01 to 0.4 mg/kg IV two to eight times daily) effectively reduces muscular spasms in large animals by enhancing GABA, but prolonged administration to a large ruminant or horse is expensive because of the short duration in the plasma and CNS. In addition to its enhancement of GABA, diazepam is efficacious because of its glycine-mimetic effects.[2208] Packing the ears with cotton to minimize auditory stimulation also can help reduce muscle spasms.

35.77.4.1.2

Ensure Good Footing

Excellent footing is essential. Tetanic animals have difficulty rising because of increased spasms and muscular tone. The stall should be bedded deeply in shavings or straw to minimize decubital ulcers.

Horses and small ruminants that cannot stand should be supported in a sling, provided they do not become frantic while suspended.

35.77.4.1.3

Eliminate the Infection

Because *C. tetani* grows in nonvascularized sites, the infection is best eliminated by surgical debridement of the affected area. Concomitant infiltration of penicillin G around the wound and parenteral administration of potassium penicillin G (22,000 IU/kg three or four times daily) or procaine penicillin G (22,000 IU/kg IM twice daily) also may be beneficial.

35.77.4.1.4

Neutralize the Unbound Toxin

Before the tetanus antitoxin has bound to the nerve cells, it is susceptible to neutralization with antitoxin. Although administration of antitoxin to animals several days after the onset of clinical signs seems to have little benefit in horses, increased survival rates have been documented in human patients who have received high dosages of tetanus antitoxin in the early phase of the disease. Infiltration of the area with 3000 to 9000 IU of tetanus antitoxin may effectively neutralize toxin that has not yet reached the peripheral vasculature. Although specific dosages have not been determined for domestic animals, suggested doses range from 1000 to 5000 IU/500-kg animal to 1000 to 5000 IU/kg.[2221–2223] The limited therapeutic benefits of intravenous antitoxin must be compared to the cost of the biologic, the potential side effects of hepatic necrosis (see Chapter 33) or anaphylaxis, and the economic value of the animal.

Some claim that administration of 50 mL antitoxin (1000 IU/mL) intracysternally to horses resulted in stabilization of the clinical signs. However, this treatment did not reverse the condition.[2224] The antitoxin is administered after slow removal of 30 mL of cerebrospinal fluid (CSF). Although a survival rate of 77% has been claimed,[2224] the study failed to consider several cysternally injected horses that died of intercurrent diseases. When all cases were considered, there appeared to be no statistically significant difference between cysternally injected horses and conventionally treated controls. Complications of this procedure included iatrogenic CSF infections, anesthesia-related deaths, and sepsis from indwelling catheters. Because of severe reactions to intrathecal equine serum in ruminants, intrathecal administration of equine-origin tetanus antitoxin is contraindicated.

35.77.4.1.5

Maintain Hydration and Nutritional Status

The patient's hydration and food intake should be monitored daily. The food should be placed off the ground in an elevated feed bunk or hay net to allow easier access. Intravenous fluids should be administered as needed to correct dehydration and electrolyte abnormalities. Alimentation with a nasogastric tube may be attempted in anorectic horses, but severe adverse reactions to this procedure in some tetanus patients may limit its usefulness. A rumenostomy in anorectic cattle relieves the chronic ruminal tympany and provides a convenient means of administering oral fluids and feed.

1090

1091

35.77.4.1.6

Establish Active Antitoxic Immunity

The concentration of tetanus toxin necessary to cause neurologic symptoms is less than that required to stimulate an active immunologic response. Affected animals should be immunized with tetanus toxoid at the time of treatment and given a second dose 1 to 2 months later. Concomitant injections of tetanus

antitoxin and toxoid should be made at different sites of the body and should not be admixed before administration.

35.77.4.1.7

Prognosis

The mortality rate may reach 50% in cattle and 80% in horses. The rate of progression of clinical signs is indirectly related to the prognosis. Animals that survive for longer than 7 days have a fair to good chance of complete recovery.

35.77.4.1.8

Prevention

Because cattle appear to be more resistant to tetanus than horses and small ruminants, they are not routinely immunized against the disease unless outbreaks have occurred previously. Colostral antibodies may interfere with the active immunization of neonates. One report indicates that most foals from immunized dams (82.9%) lose passively acquired specific antitoxic antibodies by 4 months of age. However, other studies suggest that passive immunity may last as long as 6 to 12 months of age. Because some animals have low titers and others have high, persistent titers, a general recommendation might include vaccination of livestock at 2, 3, and 6 months of age, followed by a booster after 1 year. To ensure protective levels of colostral antibodies, mares, does, or ewes should receive an annual booster dose of the toxoid 1 to 2 months before the anticipated date of parturition. One study indicated that tetanus prophylaxis was not cost-effective for sheep, but vaccination recommendations would differ, depending on the economic value of the animal at risk.[2225]

Acute hepatic necrosis of horses (Theiler's disease) has been associated with administration of certain lots of commercially prepared tetanus antitoxin (see Chapter 33) 1 to 3 months previously. Such findings indicate that administration of tetanus antitoxin should be limited to unvaccinated horses with tetanus-prone wounds. The recommended doses of tetanus antitoxin are 1500 IU subcutaneously (SC) or intramuscularly (IM) for adult horses or cattle[2226] and 500 IU SC or IM for sheep and goats. Tetanus toxoid should be administered concomitantly. The antitoxin and the toxoid should not be mixed in the same syringe and should be administered at different sites of the body; a second toxoid dose should be given in 1 month.[2226,2227] Previously immunized horses with tetanus-prone lesions should be given a booster dose of tetanus toxoid and should not be given antitoxin. Foals from unvaccinated dams should receive 1500 IU of tetanus antitoxin at birth.[2226]

Tetanus toxoid is effective, but not all horses develop protective immunity. Historical information citing a previous vaccination should not completely exclude the possibility of tetanus.[2228]

35.78

TRIARYL PHOSPHATE POISONING (CHRONIC ORGANOPHOSPHATE POISONING; DYING-BACK AXONOPATHY)

Ingestion of lubricants containing triaryl phosphates causes a neurologic disturbance of livestock characterized by a delayed neuropathy resulting in incoordination and paralysis. Common sources of the triaryl phosphate esters include turbojet lubricants, hydraulic oils, industrial solvents, plasticizers, and automotive brake fluid. Chronic organophosphate poisoning also occurs in some families of sheep after treatment with organophosphorus anthelmintics.[2229] At least six different phenotypes of sheep have been identified with respect to their ability to

metabolize carboxylic acid esters.[2230,2231] These are designated as Esa/a, Esa/b, and Esa/c (high-enzyme groups) and Esa/c, Esb/b, and Esc/c (low-enzyme groups). This genetically determined inability to inactivate organophosphates governs the appearance of demyelination after administration of therapeutic dosages of the drugs.

Triaryl phosphates have few effects on the glial cells,[2232] but they have profound neurotoxicity for the longest axons.[2233] These fibers degenerate first at the distal, nonterminal areas. The degenerative lesions then spread proximally from the terminal nerve rootlets into the spinal cord until the cell body dies (dying-back axonopathy). Dosages of triaryl phosphate ranging from 5 to 10 g/kg cause paralysis by 19 to 36 days after exposure.[2234] Cats may be poisoned by a single topical application of tri-*o*-cresyl phosphate ester at 1000 mg/kg or by daily application of 1 to 100 mg/kg,[2235] and massive topical exposure may cause toxicity in livestock. The poisoning may be cumulative because in some outbreaks, compounds containing as little as 0.4% tri-*o*-cresyl phosphaester have been found in toxic materials. Animals belonging to the low-enzyme groups are much more susceptible than their high-enzyme herdmates.

35.78.1 Clinical Signs

The onset of slowly progressive neurologic signs occurs about 10 days to a few months after exposure.[2236–2238] The clinical signs of chronic organophosphate intoxication are rough hair coat, bloat, dyspnea, muscular weakness, and incoordination of the rear legs. The animals may slip on their hindlimbs and assume a dog-sitting posture. The limbs are circumducted and lack normal conscious proprioceptive responses. Affected animals become recumbent, attempt to rise, but do so incompletely and fall. Muscular tone and flexor reflexes may be normal, or flaccid paralysis may be evident.[2237] The tail, bladder, and rectum often are paralyzed, and affected animals show signs of incontinence, constipation, and perineal scalding. Slight ventrolateral strabismus has been described, and some animals have been reported to become mute.[2238,2239] Most animals retain a normal appetite and sensorium during the development of the paralysis. Electromyographic changes in experimentally poisoned animals include increased insertional activity, positive sharp waves, and fibrillation potentials in the muscles of the hindlimb, consistent with denervation of affected muscles.[2240] Organophosphate-induced neuropathy also has been reported in horses, where the most striking clinical sign was bilateral laryngeal paralysis.[2241,2242] Degeneration similar to that caused by delayed organophasphate toxicity in other species was most severe in the recurrent laryngeal nerves, but milder changes were present in other peripheral nerves.

35.78.2 Pathology

Laboratory confirmation of the condition usually is based on histopathologic detection of a dying-back axonopathy in the peripheral nervous tissues. Clinical pathologic parameters usually are normal. The RBC cholinesterase is low or undetectable at clinical onset but may return to normal concentrations by the time the animals display profound paralysis. The specific concentration of cholinesterase depends largely on the type of organophosphate and the patient's genetic ability to metabolize the toxic compounds. Whole-blood cholinesterase concentrations in haloxon-treated esterase A–deficient animals remain significantly lower than in controls for at least 27 days after administration of 375 mg. In comparison, the enzyme concentrations in the plasma of normal sheep do not decrease after drug treatment.[2243] Cholinesterase levels in exposed animals are not predictive of the later onset of delayed neurotoxicity.[2238]

Macroscopic lesions are not usually seen. Microscopic lesions are found exclusively in the central nervous system, and their severity appears to be dose dependent. The lesions begin distally and progress retrograde along the long, unsynapsed proprioceptive and motor tracts. The dorsospinal, cerebellar, gracile, and cuneate tracts are most susceptible to the effects of the toxins.[2240] Specific lesions include demyelination, internodal axonal swelling, and wallerian degeneration. There also is a vacuolation of the large neurons of the ventral motor nucleus of the spinal cord. The mechanism of neurotoxicity is unknown, but alteration of a cell membrane protein found in neurons and some other cells has been implicated.[2243–2245] This protein has been designated a "neuropathy target esterase" and is thought to be "aged" by phosphorylation induced by the toxicosis.

Newer compounds in the triaryl phosphate group are less capable of causing delayed neurotoxicity, which offers some hope that the incidence of this type of toxicity may decline in the future.[2245] Delayed organophosphate toxicity is not treatable and is irreversible.

35.79 MOTOR UNIT AND CAUDA EQUINA DISEASES

MARY O. SMITH

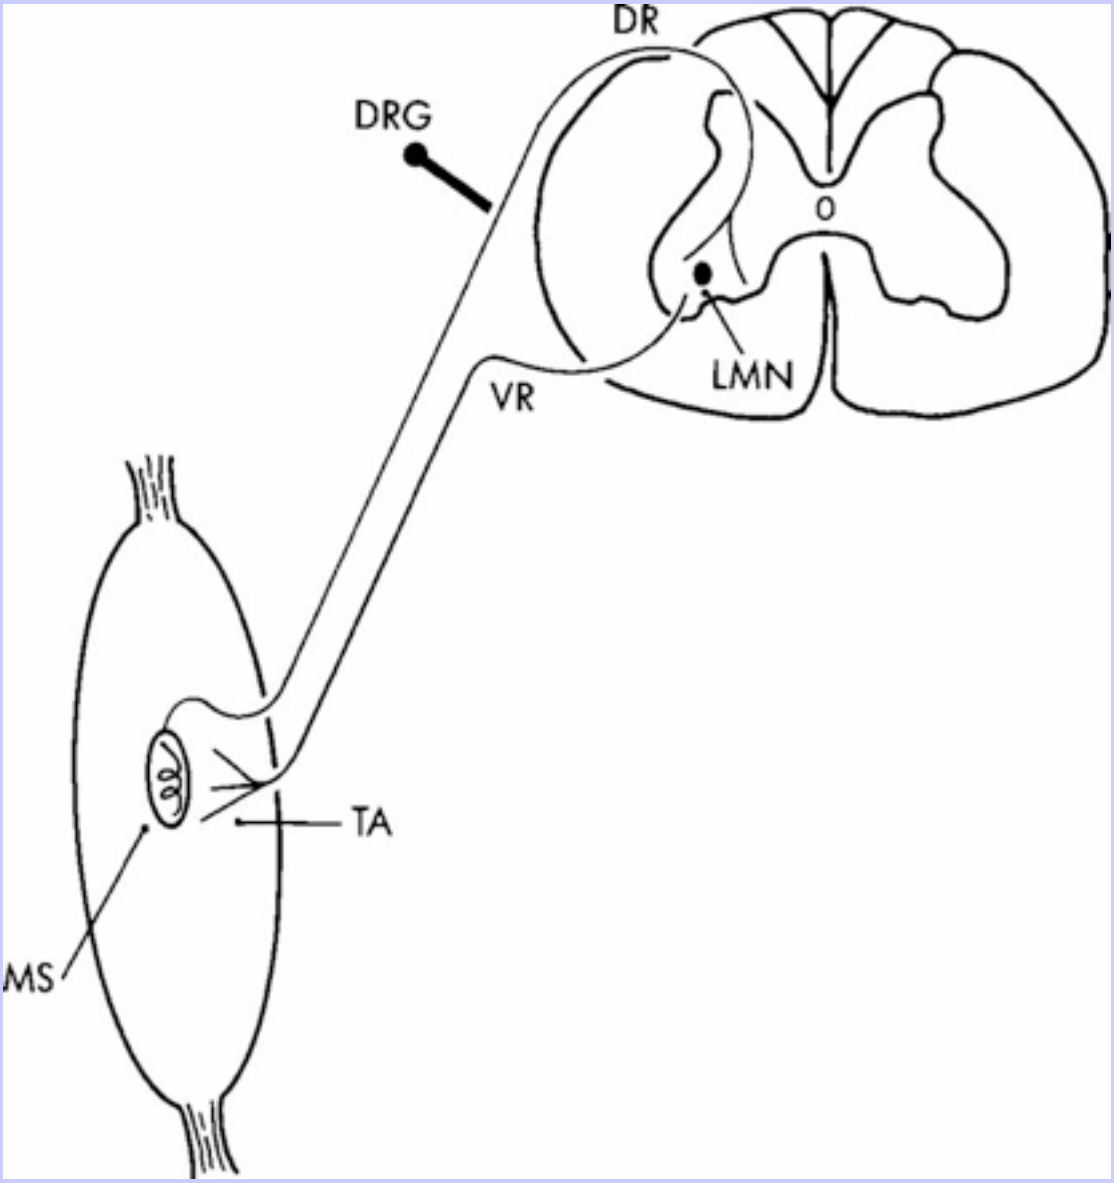
35.80 ELECTROMYOGRAPHY AND NERVE CONDUCTION TESTING IN MOTOR UNIT DISEASE

A number of electrodiagnostic techniques are now applied to the diagnosis of neurologic disease in animals. They are particularly useful when clinical signs of generalized weakness, muscle atrophy, tremors, or obscure lameness are present. Electromyography (EMG) and peripheral nerve conduction testing (NCT) are of great value for diagnosing diseases that affect the motor unit, for assessing the prognosis, and for determining the effects of therapy. EMG and NCT are simple, relatively noninvasive techniques that provide objective information on the functional status of the nerves and muscles that cannot be determined by other means.

35.80.1 Motor Unit

The motor unit is the smallest functional unit of the peripheral motor system. It comprises a single motoneuron and all the myofibers innervated by that motoneuron.[2246] In muscles in which precise control of movement is necessary, each motoneuron innervates only a few muscle fibers, whereas in large postural muscles in which fine control is not required, a single motoneuron innervates many hundreds of muscle fibers. The cell body of the alpha motoneuron lies in the ventral horn of the spinal cord or, in the case of cranial nerves, in cranial nerve nuclei in the brainstem. The myelinated axon of the motoneuron runs within the ventral root to the spinal nerve and peripheral nerves and finally terminates in small, unmyelinated terminal arborizations (Fig. 35-41). Enlargements of the ends of the terminal arborizations form the presynaptic components of the neuromuscular junctions. The postsynaptic part of the neuromuscular junction consists of a specialized region of the muscle fiber membrane. When acetylcholine release from the nerve terminal is sufficient to provoke an action potential in the myofibers, all the myofibers of the motor unit respond equally, an "all or nothing" response. Motor unit disease (lower motoneuron disease) may result from damage to any one of the following: the alpha motoneuron cell body or axon, the Schwann cells that form the myelin sheath of the alpha motoneuron, the neuromuscular junction, or the muscle fiber.

Fig. 35-41 Components of the motor unit. *DR,* Dorsal root of spinal nerve; *DRG,* dorsal root ganglion; *LMN,* lower motor neuron; *MS,* muscle spindle; *TA,* terminal arborizations of lower motor neuron axon; *VR,* ventral root of spinal nerve.



Although they are not part of the motor unit, the neurons that provide the sensory supply to the skeletal muscles may be involved in motor unit diseases in animals. Dysfunction of the peripheral sensory nerves causes clinical signs similar to those seen with motor unit disorders, even when all the components of the motor unit are normal.[2247] The cell bodies of sensory neurons lie in the dorsal root ganglia or in the sensory nuclei of cranial nerves. Their axons extend centrally to synapse with lower motoneurons and interneurons in the spinal cord and

brainstem and extend distally in peripheral nerves to the stretch receptors in the muscle spindles of skeletal muscles and to proprioceptors in joints (see Fig. 35-41).

35.80.2 Instrumentation

The recording of the electrical activity of nerve and muscle cells requires an electrode system, an amplifier, and a device to display the recording. An electrical stimulator is needed for NCT. A variety of computer-based units are now available for EMG and NCT, with a range of specifications to supply the different needs of investigators and clinicians. The components of a system may be purchased individually, but most clinicians prefer to use a complete unit. Portable units make this technology easy to use in the field, not only in hospital situations. EMG units offer a range of specializations to improve signal amplification while minimizing interference, including high- and low-frequency filters, common mode rejection (to reduce 60-Hz interference from nearby electricity sources), and signal-averaging capabilities to facilitate the recording of nerve action potentials. Data can be stored in the computer memory for later transfer to disc or other external memory and to create paper printouts. An audioamplifier is a useful addition to the system, because many of the potentials recorded by EMG produce characteristic sounds when converted to an audible signal. It is often easier for an experienced electromyographer to make a diagnosis by listening to the audio EMG than by trying to follow a series of rapidly changing potentials displayed on the cathode ray oscilloscope (CRO) screen. Programs that can analyze data (e.g., motor unit potentials) and filters that facilitate the study of periodic motion (gait) are now available.[2248–2250]

1092
1093

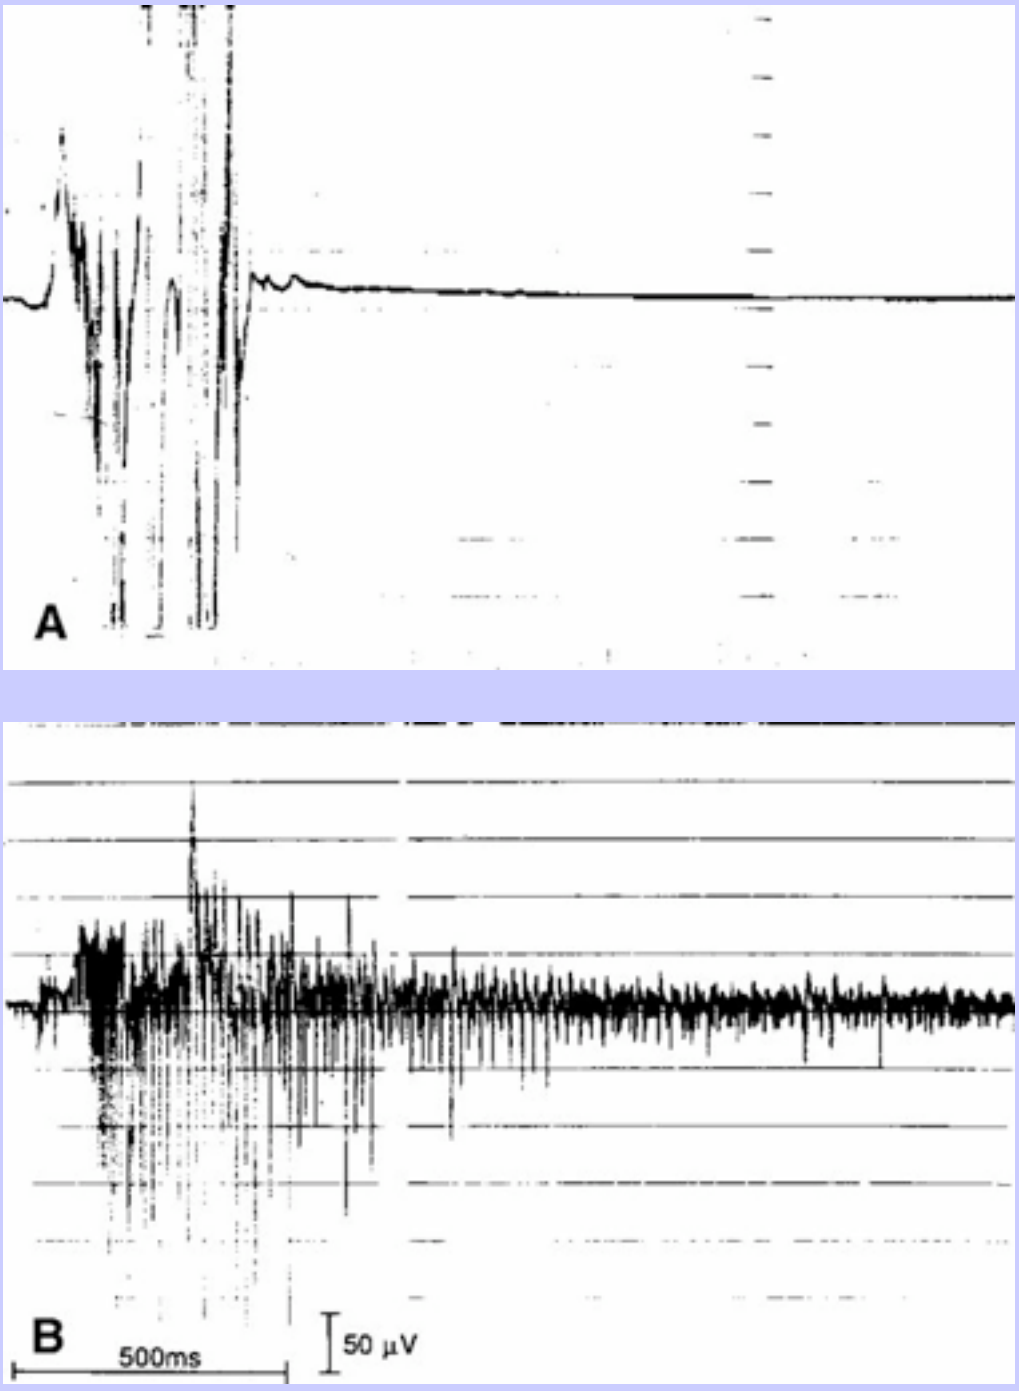
For recording, three electrodes are required: an active or exploring electrode, a reference electrode, and a ground electrode. A number of different arrangements are possible, but the coaxial needle electrode is typically used. The central wire of the coaxial electrode is the active component, and the surrounding hollow needle is the reference component. The wire is insulated from the needle along its length by a material such as Teflon, except at its tip, where it is exposed. This type of electrode is particularly suited to use in large animals because it minimizes the problem of poor electrical contact encountered with surface electrodes and does not seem to cause undue discomfort. For similar reasons, a subcutaneous needle electrode usually is chosen for the ground electrode, which is placed a short distance from the recording and reference electrodes, usually over a bony prominence. Surface electrodes can be used to study activity in muscles during exercise, both to determine the presence of disease and to direct training exercises where development of particular muscles is desired.[2251,2252]

35.80.3 Electromyography

Electromyography usually can be performed in a conscious animal, although some restraint is necessary, such as placing the animal in stocks and administering a sedative agent. General anesthesia may be necessary for EMG in extremely fractious animals, but not without significant risks, particularly when animals are weak and may have difficulty rising after anesthesia. Caudal epidural anesthesia may offer a safer alternative when examination of hindquarter muscles alone is deemed adequate for evaluation.[2253] Common sedatives such as xylazine and acepromazine do not interfere with EMG. An electromyographic examination should include testing of many muscles over the whole body, focusing on those thought to be involved in the disease process. The recording electrode must be inserted into four or five sites in each muscle tested to ensure that focal abnormalities are not missed.

Electromyography alone usually does not provide a definitive diagnosis of the disease process present. EMG does help to localize the lesion and provides information that can then be used in selecting further diagnostic modalities (e.g., NCT) and the most suitable site for muscle or nerve biopsy.

Fig. 35-42 Electromyogram insertion activity. **A,** Normal: insertion activity ends abruptly when movement of the exploring electrode stops. **B,** Abnormal: insertion activity persists after the exploring electrode is at rest.



35.80.4 Normal Muscle

35.80.4.1 INSERTION ACTIVITY

Insertion of the recording electrode into a muscle or its movement in the muscle results in a burst of electrical activity that stops abruptly when movement of the electrode stops (Fig. 35-42). It is accompanied by a harsh, crackling sound. This “insertion activity” is the result of direct stimulation of muscle fibers by the moving electrode.

35.80.4.2 ELECTRICAL SILENCE

When the electrode is motionless in a normal resting muscle (one that is not actively contracting), no electrical activity is seen on the electromyograph. The electron beam of the CRO traces a straight line, and the audio electromyograph is silent. Electrical silence is the normal state in resting muscle except in the endplate zone.

35.80.4.3 MOTOR UNIT ACTION POTENTIAL (MUAP)

An MUAP is the electrical activity of a single motor unit (Fig. 35-43). Only the activity of the fibers lying within approximately 1 mm of the electrode tip is recorded.[2254] MUAPs may be observed during EMG of normal active muscle. The parameters of an MUAP vary with the motor unit that produced it, with the type of electrode arrangement and electromyograph used, and with the position of the electrodes in relation to the electrical event itself. The important characteristics of the MUAP are the amplitude, duration, and number of phases. Normal MUAPs are biphasic or triphasic with amplitudes of 500 to 3000 μV and durations of 3 to 15 msec.[2254,2255] In very active muscles, many MUAPs are superimposed, producing “interference patterns.” This may be observed in the limb muscles of a standing animal.

35.80.4.4 MINIATURE ENDPLATE POTENTIALS (MEPPS)

The neuromuscular junctions of the myofibers of one muscle tend to lie in a band across the midpoint of the muscle fibers; this region is called the endplate zone. The spontaneous release of quanta of acetylcholine from the nerve terminal at a neuromuscular junction results in local electrical responses in the muscle fiber. This activity can be recorded when the recording electrode lies close to the neuromuscular junction in the endplate zone (Fig. 35-44). MEPPs are monophasic-negative potentials having amplitudes of 10 to 20 μV and durations of 0.5 to 1 msec.[2256] MEPPs are local electrical responses in the muscle fiber that are not propagated throughout the whole fiber and thus do not result in fiber contraction. MEPPs are present even in resting muscle and are normal. MEPPs may be absent in disorders in which acetylcholine release is lacking from the nerve (neuropathies), in those with an abnormality in transmission across the neuromuscular junction (junctionopathies), and in some myopathies. MEPPs cannot be detected when the recording electrode is not close to a neuromuscular junction.

Fig. 35-43 Motor unit action potentlals. **A,** Normal: amplitude is approximately 550 µV. **B,** Abnormal: amplitude is decreased by approximately 200 µV.

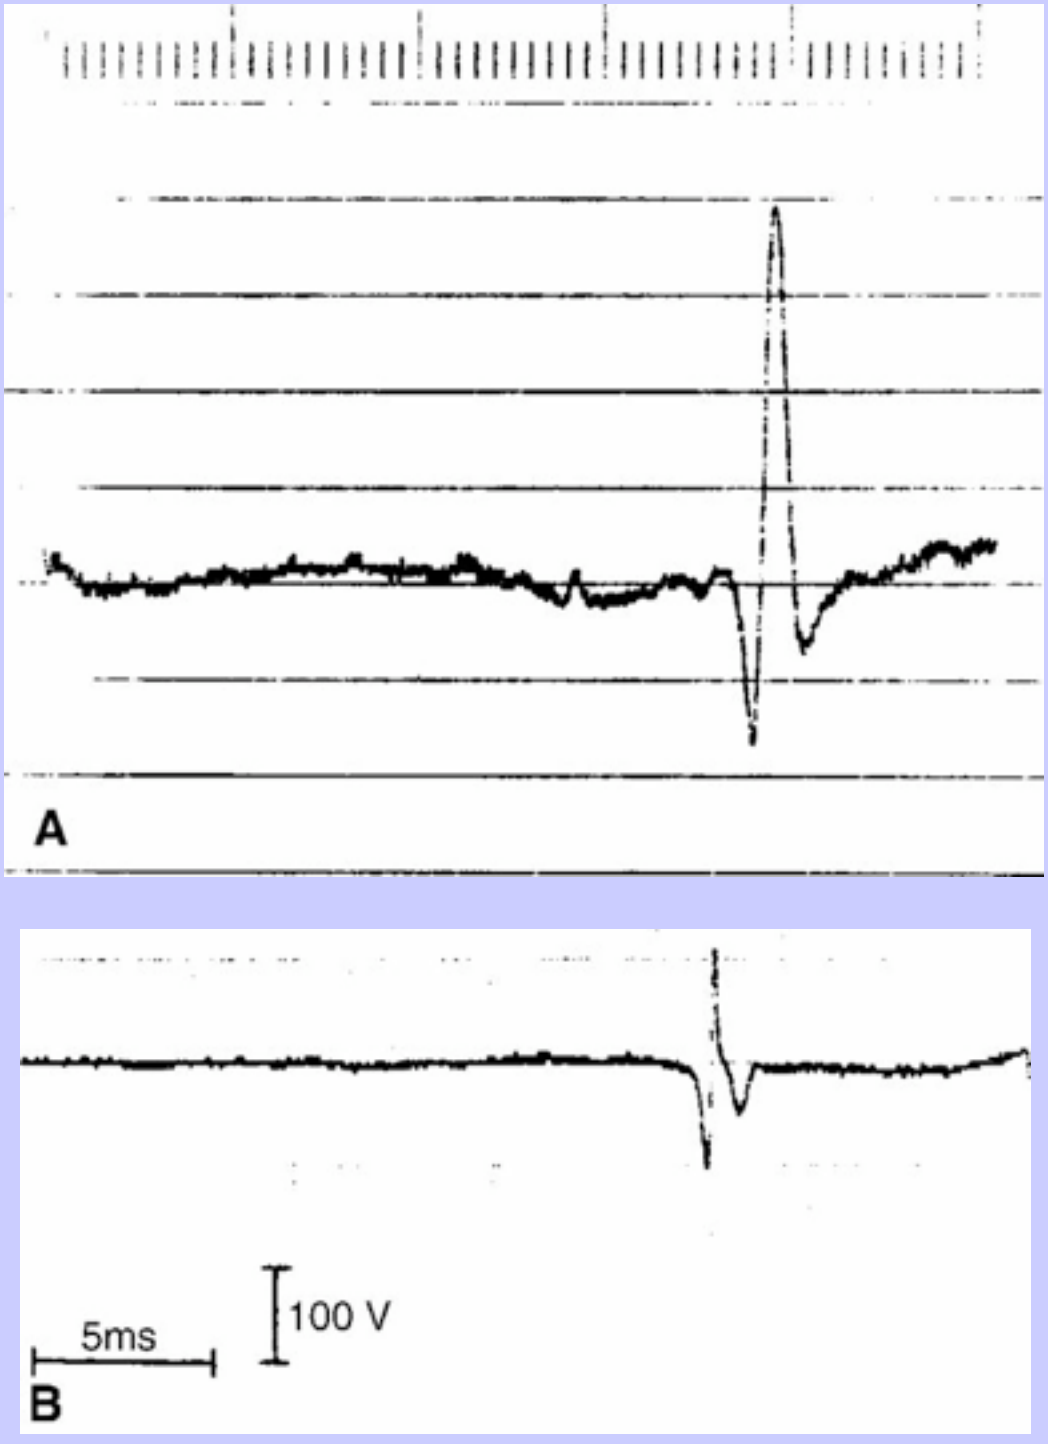


Fig. 35-44 Miniature endplate potentials (MEPPs). MEPPs are a normal electromyographic finding.

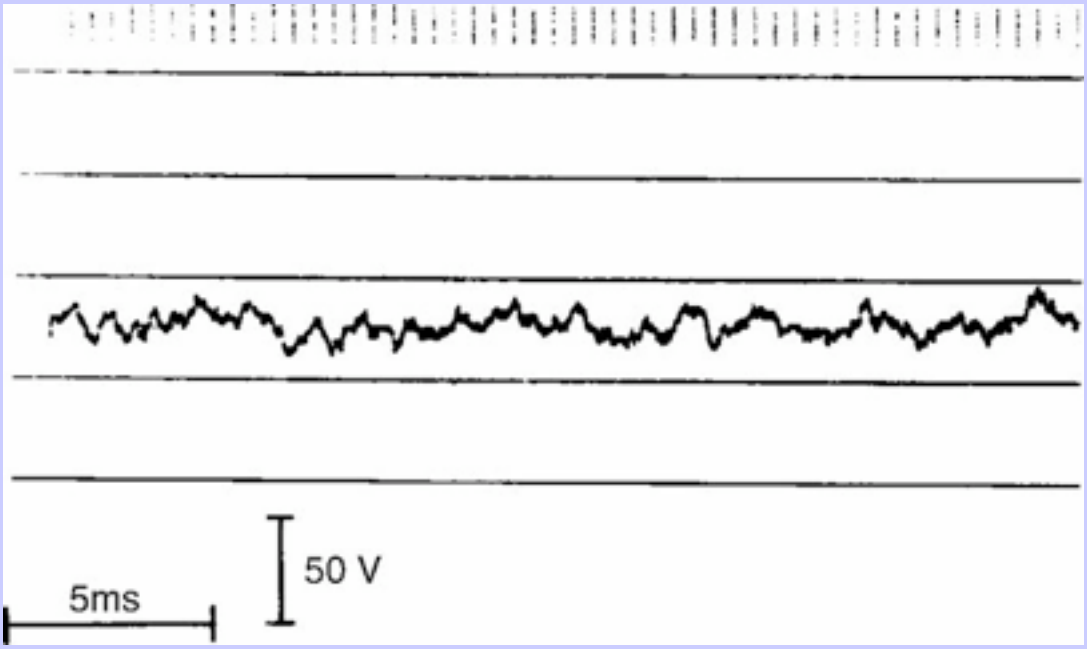

Fig. 35-45 Abnormal electromyographic potentials. **A,** Positive sharp waves. **B,** Fibrillation potentials.

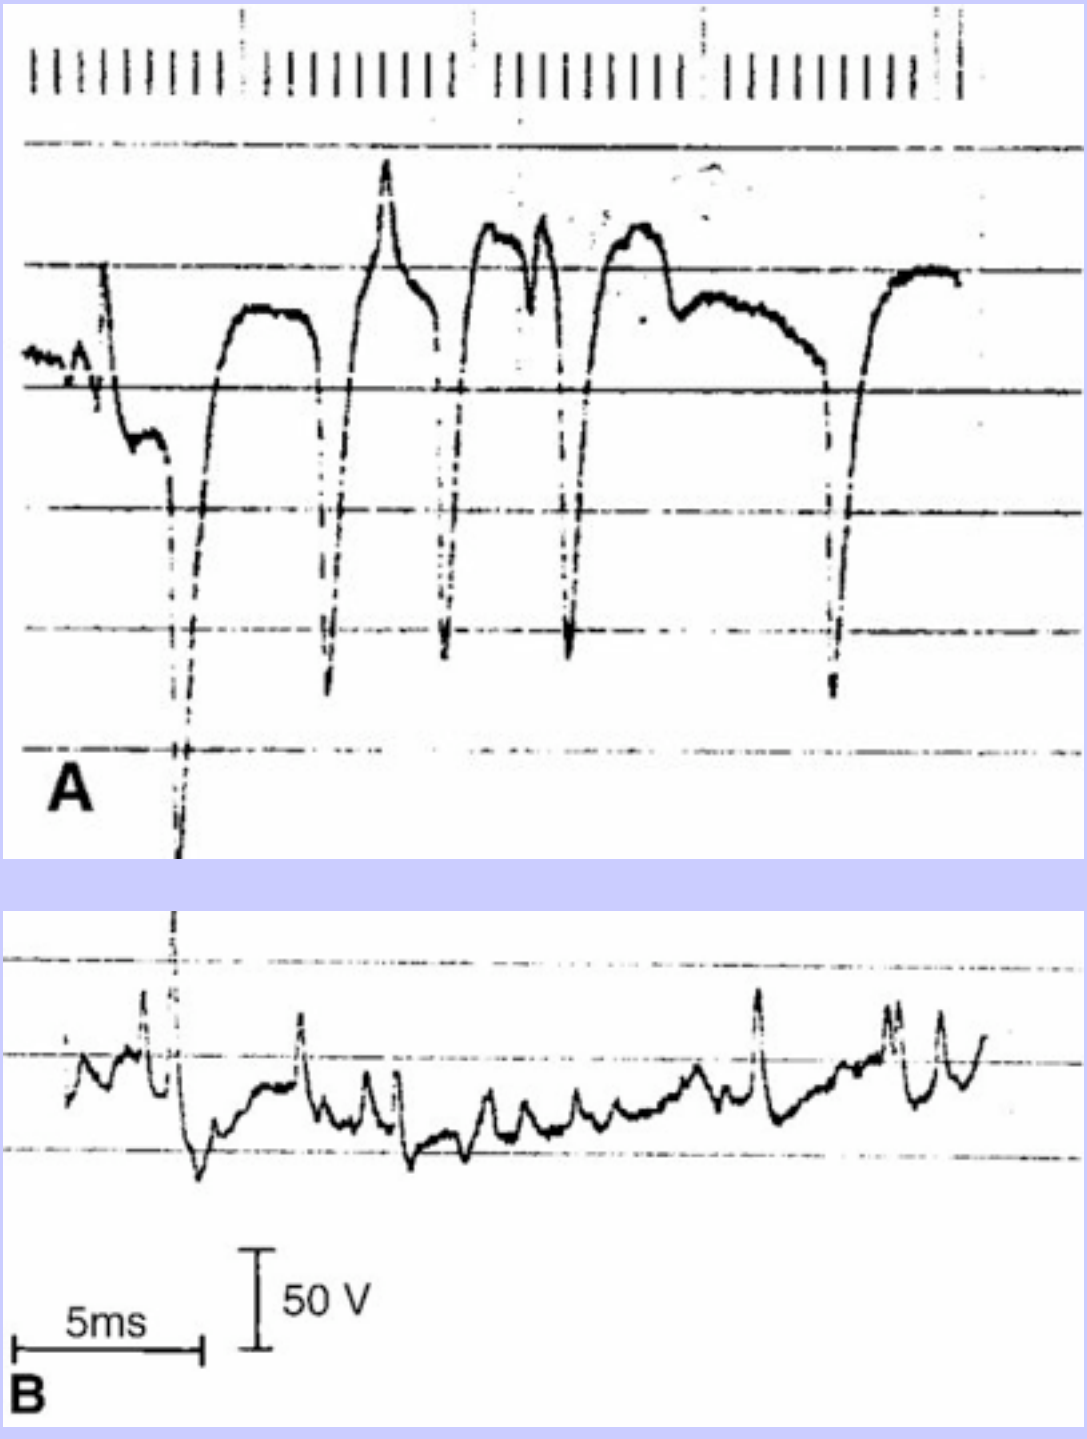

Age of the patient has been shown to have an effect on EMG findings, even in animals that are clinically healthy. Insertional activity, spontaneous activity, and motor unit morphology all have been shown to differ in elderly horses (>18 years old) compared with young and adult horses, with the elderly horses displaying a greater amount of EMG activity usually considered to indicate muscle pathology.[2257] This factor must be taken into account when interpreting EMG findings.

35.80.5 Abnormal Muscle

35.80.5.1 INSERTION ACTIVITY

In both neuropathic and myopathic diseases, insertion activity may be prolonged or occasionally reduced (see Fig. 35-42). Either of these findings is evidence of abnormality. Abnormalities in EMG recordings caused by neuropathic disease do not begin to appear until approximately 5 days after the onset of the neuropathy.

35.80.5.2 MOTOR UNIT ACTION POTENTIALS

In both myopathies and neuropathies, changes in the characteristics of MUAPs occur. These include reductions in amplitude, polyphasia, temporal dispersion, and even absence of MUAPs.

After damage to some nerve fibers, others may undergo collateral sprouting, where new terminal arborizations grow and innervate denervated myofibers. The net result of this process is an increase in the size of the motor unit. The MUAPs of these large motor units have correspondingly larger amplitudes and thus are called giant MUAPs (see Fig. 35-43).

Quantitiative analysis of MUAPs adds another level of sophistication to EMG examination.[2248,2250] Characteristics of MUAPs in healthy horses include amplitude, duration, and number of phases turns within the MUAP. Changes in these characteristics are found when either myopathy or neuropathy are present.[2258]

35.80.5.3 FIBRILLATION POTENTIALS AND POSITIVE SHARP WAVES

These activities result from the electrical activity of single muscle fibers (Fig. 35-45). The muscle activity may be spontaneous or the result of mechanical stimulation of the fiber by the electrode. It is thought that the occurrence of spontaneous individual fiber contraction is a manifestation of an increase in the excitability of the muscle fiber membrane. Fibrillation potentials and positive sharp waves occur in both neuropathies and myopathies. The presence of either activity is not pathognomonic for the type of pathologic condition present.

1094 1095

Fibrillation potentials are biphasic spikes with an initial positive phase. Their peak-to-peak amplitude is less than 1 mV and their duration less than 5 msec.[2256] Fibrillation potentials are recorded when the recording electrode lies a short distance from the muscle fiber whose activity is being recorded.

Positive sharp waves have an initial positive phase with amplitude of up to 1 mV and duration under 5 msec, followed by a negative phase with lower amplitude and a duration of 10 to 100 msec.[2256] They are recorded when the recording electrode tip lies close to the electrically active myofiber.

In addition to EMG changes induced by primary myopathic and neuropathic disease, electrolyte disturbances such as hypocalcemia and hypomagnesemia also have been shown to result in EMG abnormalities, both inducing spontaneous muscle activity and altering the waveform characteristics of MUAPs.[2259] Therefore, a complete history, physical examination and serum chemistry are essential for correct interpretation of EMG findings.

35.80.6 Nerve Conduction Testing

Nerve conduction studies usually require that the animal be sedated or under general anesthesia, because the procedure is somewhat painful. Routinely used sedatives and anesthetic agents do not interfere with the results of testing. Two stimulating needle electrodes, the anode and cathode, are placed on or close to the nerve to be stimulated. A short pulse of current is applied to the nerve. A compound nerve action potential (CNAP) is evoked in the nerve by the applied current and is propagated along the nerve in the same manner as a naturally occurring action potential. Either the CNAP is recorded directly from the nerve itself, or the compound muscle action potential (CMAP) evoked in the muscle innervated by that nerve is recorded. To ensure that all the nerve fibers are stimulated, the stimulus intensity is varied to determine the maximum stimulus (i.e., the current that just evokes the maximum CNAP or CMAP). A supramaximum stimulus (150% to 200% of the maximum stimulus) is applied when making recordings.[2255,2260]

35.80.6.1 MOTOR NERVE CONDUCTION (MNC)

MNC is determined by stimulating a mixed peripheral nerve such as the radial or median nerve and recording the CMAP evoked in a muscle innervated by that nerve. By recording the CMAP evoked by stimulating the nerve, only the activity of the alpha motoneurons in that nerve is evaluated. The latency between the application of the stimulus and the onset of contraction of the muscle can be broken down into three components: the time for conduction of the action potential in the nerve, the time for neuromuscular transmission, and the time for conduction of the muscle action potential from the neuromuscular junction to the vicinity of the recording electrode. By stimulating the nerve at two or more points, the latter two variables can be eliminated from the calculation and the velocity of conduction of the nerve action potential between the stimulus points determined.

35.80.6.2 SENSORY NERVE CONDUCTION (SNC)

SNC is determined by stimulating a purely sensory nerve peripherally (e.g., palmar digital nerves)[2260] and recording the CNAP from the same nerve at a more proximal point. Because the amplitude of the CNAP is relatively small, usually less than 1 mV, the technique of signal averaging is used; the responses to repeated stimuli are recorded and electrically averaged, eliminating background electrical activity that otherwise would obscure the evoked potential.

Physiologic alterations in nerve conduction must be differentiated from pathologic changes. Cooling of the nerve results in a slowing of conduction velocity.[2261] Therefore it is important to monitor limb temperature when doing NCTs to avoid erroneous interpretation of results. Heating pads and lamps can be used to maintain normal temperature. Conduction velocity of the action potential in the nerve is proportional to fiber diameter. In ponies and dogs, nerve conduction velocity is faster in the proximal portion of the nerve because of the greater diameter of the proximal regions of peripheral nerves.[2262] SNC velocity is slower in horses

than in ponies because of distal tapering of peripheral nerves.[2261] Nerve conduction velocity is slower in young and aged dogs than in mature adults.[2263] This finding is probably true for all species.

Specific techniques for peripheral nerve testing in the horse have been described, and normal values for both MNC and SNC velocities have been determined for a number of peripheral nerves.[2260,2261,2264] Nerve conduction velocity, amplitude, and waveform characteristics all provide valuable information on the functional status of the nerve. In pathologic conditions, changes in nerve function occur that depend only on the nature of the pathologic process in the nerve, not on its etiology.

35.80.6.3

SLOWING OF NERVE CONDUCTION

Reduction in the velocity of nerve conduction is the result of segmental demyelination, which may occur in sensory or motor fibers or both. Demyelination may be present as the sole pathologic change or may be accompanied by other neuropathologic processes. No pathologic significance has been attributed to increased conduction velocity; it is the result of technical error.

35.80.6.4

INCREASED TEMPORAL DISPERSION

Increased temporal dispersion of an action potential also results from segmental demyelination and differences in the rate of conduction in individual nerve fibers. For example, if some fibers are normal and some are undergoing demyelination, increased dispersion of the action potential is recorded, whether a nerve or a muscle action potential. In this case, because some nerves are normal, the nerve conduction velocity calculated will be normal.

35.80.6.5

REDUCTION IN AMPLITUDE

The amplitudes of the CNAP and the CMAP depend on the number of functional neurons stimulated. The CMAP also depends on the number of functional myofibers in the motor unit and on the functional integrity of the neuromuscular junctions. Because different complements of neurons are present in different nerves and in the same nerve in different animals, and also because the size of muscles themselves varies, it is not possible to determine absolute parameters for the amplitude of CNAP or CMAP. However, qualitative evaluations of amplitude can be made. Reduced amplitude of nerve action potentials is seen as a result of primary axonopathy (wallerian degeneration), junctionopathy (e.g., botulism), and nerve conduction block in some demyelinating diseases.[2265] Reduction in the amplitude of the CMAP also may be caused by primary muscle disease, resulting in a reduction in the number of functional myofibers.

35.80.6.6

POLYPHASIA

In cases of collateral sprouting, the resulting larger motor units are distributed more widely in the muscle. Some of the nerve terminal arborizations are longer than others; therefore the nerve action potential does not arrive at all the neuromuscular junctions at the same time. A polyphasic waveform in the CNAP results.

Electromyography and NCT are valuable aids to the diagnosis of motor unit disease in animals. Although they provide considerable information about the nature, extent, and progress of pathologic changes, they do not define the etiology of those changes. Further diagnostic procedures, such as muscle or nerve biopsy, CSF analysis, and serologic testing, are required to arrive at a specific diagnosis.

1095 1096

35.81 BOTULISM (SHAKER FOALS; FORAGE POISONING)

ROBERT H. WHITLOCK

35.81.1 Definition and Etiology

Botulism spores are ubiquitous in the soil in most areas of the United States and cause isolated occurrences of botulism in humans, animals, birds, and fish.[2266] The clinical signs of botulism result from the effect of the neurotoxin, an exotoxin produced by *Clostridium botulinum,* on the myoneural junction, leading to progressive muscular weakness.[2267–2272] Seven neurotoxin types have been identified: A, B, C, D, E, F, and G.[2273,2274] In North America, horses are most often affected by type B botulism (>85% of cases) and occasionally by types A and C toxins.[2275,2276] Types A and B botulism are associated with forage or hay and do not involve an animal carcass. Type A cases have been reported in California, Utah, Idaho, Oregon, and Ohio, but almost never in the mid-Atlantic region.[2275] Type C toxin is typically associated with a decomposing carcass,[2276] feeding poultry litter,[2277] or situations where ravens or crows feed on a decomposing carcass, then transport toxin to the feed buckets or feed troughs of horses.[2277,2278]

Type D botulism occurs more frequently in South America and South Africa and has been linked to phosphorus-deficient cattle chewing bones of decaying carcasses to restore their phosphorus stores.[2279,2280] Feeding poultry litter to cattle in North America,[2281,2282] Europe, Israel,[2283–2285] and Australia[2286] has been associated with type D botulism, often in massive outbreaks.[2287–2294] More recently, type D botulism was confirmed in a group of beef cattle in Canada being fed bakery waste,[2295] then later in dairy cattle in Canada.[2296]

Recently, types C and D botulism have been reported in Switzerland horses.[2297] Type E botulism in humans[2273,2274] is typically associated with fish, but rarely reported in animals. Birds that eat fish with type E botulism have recently been reported in areas surrounding lakes Erie and Ontario.[2298] Types F and G have rarely been reported in humans.[2274]

Clinical botulism occurs by one of three routes: (1) ingestion of the preformed toxin (the most common form in cattle and adult horses), (2) ingestion of spores, leading to toxicoinfectious botulism (shaker foal syndrome), and (3) wounds contaminated with botulism spores and subsequent production and absorption of the neurotoxin. Wound botulism occurs in horses, most often in castration sites,[2299] umbilical hernia repairs (typically with hernia clamps), or deep puncture wounds that occur with injections of counterirritants.[2300] Horses are much more susceptible to botulinum toxin than cattle. If botulinum-containing forage is fed to both horses and cattle, the horses will develop clinical signs first, and usually more horses will be affected than cattle.[2301] This likely results from degradation of toxin by the rumen microbes,[2302] whereas horses have more time to absorb the toxin from the intestinal tract before the toxin reaches the colon, the site of microbial degradation.

35.81.2 Clinical Signs in Foals (“Shaker Foal Syndrome”)

The owner's chief complaint is often that the foal is found lying down more than normal. When forced to rise, it stands for a few moments, develops generalized muscle tremors (“shaker foal syndrome”), then drops to the ground, usually in lateral recumbency.[2303,2304] Some foals present with colic, whereas others present with pneumonia or respiratory distress.[2305] Closer physical examination usually reveals a well-nourished foal that is bright, alert, and has normal vital signs and normal clinical pathologic findings, which help to differentiate botulism from other diseases. Affected foals often drool milk from their mouth when suckling the mare. Decreased tongue tone is evidenced by the tongue being easier to pull from the mouth than normal and the foal slowly retracting the tongue when released.[2306] Mild mydriasis and weak eyelid tone may be detected in most foals. Progressive symmetric myasthenia, along with the absence of fever and other signs of systemic disease leading to recumbency, remains the predominant clinical sign. Constipation and ileus are consistent findings.[2307] As the disease progresses, the heart rate and respiratory rate increase, which may progress to inhalation pneumonia and terminate in respiratory failure. A small proportion of foals will stabilize at a certain level of neuromuscular weakness and then gradually recover over 10 to 14 days with intensive nursing care. Although botulism may occur at any age, the peak age of occurrence is 4 weeks, with 70% of cases occurring between 2 and 6 weeks of age.[2308]

35.81.3 Clinical Signs in Adult Horses History

Generalized muscle weakness (myasthenia) and dysphagia are typically the first clinical signs of botulism in adult horses detected by an alert horse owner. Astute individuals may detect subtle early signs of botulism, including changes in the horse's attitude (slight depression) and decreased exercise tolerance. This is especially true after a few cases of botulism have occurred on their premises.[2309] Other early signs include slowness to eat, with reduced ability to swallow hay and water. Colic may be the initial clinical sign, presumably from ileus and accumulation of gas.[2310–2313] Occasionally, the pain will be severe enough that an experienced clinician recommends general anesthesia with surgical intervention, later to determine the pain was attributable to botulism. Draft horses have reduced work capacity, leading to progressive weakness, dysphagia, and recumbency. Some owners may not seek veterinary attention until the horse is recumbent.

35.81.3.1 PHYSICAL EXAMINATION

35.81.3.1.1 Decreased Tongue Tone

Characteristic early signs of botulism include reduced tongue strength. Assessment of tongue strength is best done by keeping the jaws closed with the left arm under the jaw, then placing the hand on the top of the nasal bones. The tongue is gently retracted with the other hand through the interdental space and allowed to hang down, then slowly released. Most normal horses quickly retract the tongue into the mouth after release with one or two “tugs” or attempts to retract the tongue.[2310] The strength of the normal tongue retraction response varies significantly from horse to horse and must be considered when assessing tongue strength in a suspect horse. In more advanced stages of the disease, but before recumbency, the horse will retract the tongue very slowly, if at all (Fig. 35-46). This procedure, the “tongue stress test,” if done properly, represents one of the earliest and most sensitive clinical signs of botulism in horses.

35.81.3.1.2

Botulism Grain Test

The horse is offered 8 ounces of sweet feed in a large, flat feeding tube on the ground. The horse is timed and observed for ability to consume the feed. Most normal horses will consume an 8-oz cup of grain (sweet feed) in less than 2 minutes, often in less than 1 minute.[2313] In outbreaks of equine botulism, owners should be taught to perform the grain test and the tongue stress test to detect early signs of botulism and allow early treatment of affected horses. As the ability to retract the tongue diminishes, the time required for the horse to eat sweet feed increases. Grain mixed with some saliva often falls out of the mouth through the horse's lips while eating. This creates a row of grain in the feed tub and a ring on the horse's lip. This is very characteristic of botulism and is one of the earliest clinical signs[2313] (Fig. 35-47).

35.81.3.1.3

Dysphagia

Horses with beginning dysphagia may eat hay but have difficulty swallowing it. Inability to swallow water occurs after the loss of the ability to swallow hay. Horses seem to respond differently to the inability to drink water; many refuse to attempt to drink, whereas others immerse their muzzles under the surface of the water. Decreased tongue strength and dysphagia typically occur before onset of obvious muscle weakness. Recumbent horses with botulism are very difficult to assess with regard to swallowing ability because the struggle to stand takes priority over eating and drinking. During an outbreak of botulism in a herd of horses, if one horse is recumbent, it is always advisable to assess tongue tone on the other horses to detect early cases of botulism.

1096

1097

Fig. 35-46 Horse with very weak tongue. The tongue may hang over the lips for several seconds, up to a minute or longer in severe cases. This test is not specific for botulism, but is characteristic, and with other compatible clinical signs, strongly suggests botulism.

Fig. 35-47 **A,** Abnormal “grain test,” showing sweet feed mixed with saliva falling out of the side of the mouth. **B,** Note the trail of grain on the bottom of the bucket.

35.81.3.2

OTHER SIGNS AND PROGRESSION OF DISEASE

Decreased eyelid and tail tone may be detected in affected horses; however, the variation in tail tone from horse to horse makes this assessment problematic. Moderately affected horses walk with a shuffling gait, occasionally dragging their toes, and show evidence of muscle weakness. As the disease progresses, the dysphagia becomes more complete and the myasthenia more obvious, often with muscle tremors leading to recumbency and difficulty rising. Although the rate of progression can vary and is toxin dose dependent, clinical signs of botulism are always symmetric and gradually progressive, often leading to recumbency, followed by death from respiratory paralysis or euthanasia for humane considerations.

Vital signs, including capillary refill, are normal in the early stages of the disease. Once the horse is recumbent, both the heart rate and respiratory rate increase in proportion to the intensity of the struggle to rise and severity of the disease. Borborygmal sounds are gradually diminished as affected horses eat less. In the early phases of type C botulism, the character of the respiratory effort changes; the respiratory rate does not increase, but the expiratory effort becomes more exaggerated, with a prolonged abdominal lift. This unusual respiratory effort rarely occurs with other types of botulism, which helps to differentiate type C from types A and B in horses.[2298]

1097

1098

Moderate mydriasis is an early sign that persists for several days, with a sluggish pupillary response to light persisting for up to several weeks. Muscle trembling and inability to lift the head are two additional but inconsistent signs of type C botulism. The muscle trembling often starts in the triceps and extends to other large muscle groups. As the disease progresses, some horses have increased difficulty lifting their heads, and their head carriage becomes lower and lower. Massive edema of the muzzle and face may interfere with breathing, primarily in type C botulism. Supporting the head in a sling several hours at a time may result in some relief. Affected horses, when treated with botulism antitoxin, gradually regain strength to lift their heads over 7 to 14 days.[2313]

During examination of 40 horses with type C botulism in a California outbreak, dysphagia was not readily apparent or detected.[2314] The absence of dysphagia in these horses with confirmed type C botulism is unexplained. Horses in Canada,[2311] a Florida foal,[2315] and horses with experimentally induced type C botulism[2298] all had evidence of dysphagia. Some California horses that recovered from botulism had unusual prominent muscle atrophy of the supraspinatus and gluteal muscles. The atrophy was still apparent after 2 months but had healed by 5 months in four of the seven surviving horses.[2314] This previously unreported type of muscle atrophy also has not been reported since this case.

The higher the dose of botulinum toxin present at the neuromuscular junction, the more rapid is the progression of the clinical signs and the poorer the prognosis for survival. Low levels of toxin (10^3 mouse lethal dose [MLD] units) result in a more gradual onset of clinical signs, which progress over 5 to 10 days and exhibit reduced severity of signs. Mildly affected horses may only have transient dysphagia and recover with minimal treatment. Larger doses of toxin (10^8 MLD units) result in peracute, rapidly progressive illness. These horses may become recumbent within 8 to 12 hours of the first detectable signs. In herd outbreaks of equine botulism, cases may continue to develop up to 14 days after removal of the suspect feed source.

Adult recumbent horses are more difficult to manage medically than foals and therefore also have a worse prognosis for survival (<15%). Once an adult horse is recumbent as a result of botulism and unable to rise, the prognosis for recovery is poor, despite the most intensive care, including mechanical ventilation.[2300]

Some horses, however, quickly learn to adjust to their muscular weakness and do not object to being recumbent. These horses may stabilize at a certain point and gradually improve over time, but may develop massive decubital sores, even when bedded deeply with straw. Terminally ill horses paddle their legs in an intermittent struggling manner and die of respiratory distress from paralysis of the diaphragm. Euthanasia is recommended when horses are recumbent, unable to rise, and have respiratory compromise.

35.81.4 Clinical Signs in Cattle

35.81.4.1 HISTORY

Most clinical cases of botulism in cattle occur as a herd outbreak, whereas botulism in horses most frequently occurs as a single case. In cattle the veterinarian is usually called to evaluate several down cows that may have initially responded to treatment for hypocalcemia, but then relapsed.[2316] These downer cows are often not associated with recent parturition. Multiple cattle in a herd with clinical signs similar to milk fever and evidence of progressive muscular weakness typify many outbreaks of botulism in cattle. Affected cattle are anorexic and hypogalactic and may develop paraparesis, which leads to recumbency. Affected cows have decreased strength and frequency of rumen contractions and firm feces.[2317]

Further investigation of the herd outbreak usually finds a point source of botulinum toxin. Recent feeding of small grain silage such as barley, ryelage, oatlage or wheatlage stored in large plastic bags is often present 3 to 4 days before onset of clinical signs. In some outbreaks the plastic covering the forage may be damaged, allowing mold and spoilage to occur, which may lead to anaerobic conditions with botulism spores producing toxin. Ryelage and haylage stored in plastic bags or in long plastic tubes are major risk factors for botulism in cattle.[2318] Corn silage is rarely associated with botulism; however, spoiled corn silage with a pH above 5.0 has been reported as a source of botulism for cattle.[2318]

Occasionally, the incorporation of an animal carcass during the silage-making process may lead to an outbreak of botulism. Cats, dogs, and poultry carcasses are typical sources that lead to type C botulism. In one California outbreak, feed contaminated with a cat carcass was responsible for the death of more than 420 adult cattle in 1 week.[2276] Poultry litter containing decomposing chicken carcasses may also predispose cattle to either type C or D botulism.[2282,2285,2286,2319] Repeated occurrences of types C and D botulism in beef cattle have occurred in West Virginia, Arkansas, and other states where feeding poultry litter–based rations is common.[2316]

35.81.4.2 TONGUE TEST

Reduction in tongue strength has been reported as the most important clinical sign of botulism in cattle.[2320] A tongue stress test assesses three aspects of tongue muscular strength. First, insert your right hand and fingers through the interdental space while your other arm and hand keep the jaws closed. Assess the tongue muscular tone by reaching back in the mouth and putting pressure on the base of the tongue. Normally, the tongue is firm and relatively turgid. Softness and lack of tongue turgor indicate weakness. Second, grasp the tongue and pull it out the side of the mouth to test lingual strength. Normally, it not easy to grasp or pull the tongue out of a cow's mouth. Third, with the jaws held closed, slowly release the tongue from your grasp, allowing it to hang out of the side of the cow's mouth. Normally, when the tongue is pulled out of the side of

the mouth with the jaws closed, most cows quickly retract the tongue back into the mouth. If the tongue rests limply over the lip, even for a few seconds, this is very abnormal and suggests a very weak tongue.

In herds experiencing a botulism outbreak, some cattle in herds experiencing botulism will appear normal but have decreased tongue strength and reduced jaw tone; these affected cows are early in their clinical course. Rating the tongue strength of all the exposed animals allows treatment decisions regarding which cows are candidates for prophylactic treatment with botulism antitoxin. Tongue weakness is not specific for botulism, but is characteristic. Reduction in tongue strength has been considered as the most important clinical sign in cows with botulism.[2320] Rarely do cows with botulism protrude their tongue spontaneously.

If tongue strength is normal, another cause for the weakness should be considered. Decreased lingual strength may occur with listeriosis and other causes of hypoglossal nerve injury. In cases of botulism, tongue weakness is symmetric and often associated with dysphagia and progressive muscle weakness, with several animals typically involved in the same herd. During a herd outbreak of type D botulism in Ontario, the tongue test was assessed as normal, and affected cows did not have evidence of dysphagia.[2296]

35.81.4.3

JAW MOVEMENT AND MUSCLE TONE

1098

1099

In addition to tongue strength, one should also assess the masseter muscle strength by lateral movement of the mandible. Masseter muscle strength is best assessed by grasping the mandible in the area of the symphysis, then moving it laterally to determine tone of the masseter muscles. In cattle with botulism, little resistance is encountered, and the jaw seems very loose compared to normal cattle. Cows with listeriosis may also have weak masseter muscles.

35.81.4.4

PUPILLARY RESPONSE AND DYSPHAGIA

Botulism-affected cattle have pupils that tend to be dilated and poorly responsive to light. The animals may drool saliva because of their inability to swallow. These cattle rarely develop severe acidosis, as may occur with listeriosis. Often, botulism-affected cattle appear to prehend hay or grass, chew, and then swallow. However, on closer examination, the affected cow continually chews the same cud for hours without swallowing. Examination of the pharynx or oral cavity may reveal evidence of chewed hay cud or a forage bolus resulting from the inability to swallow.

Drooping ears have been reported in cows with botulism,[2320] but as with tail weakness, this sign is subjective. Additionally, pricking the skin with a needle often results in no or minimal response. Botulism-affected cattle are dull, depressed, lethargic, and often become dehydrated because of the inability to swallow. They closely resemble cattle with milk fever, except with botulism, multiple cows are involved at the same time. Animals may show muscle tremors and truncal ataxia, even to the point of dribbling urine, before becoming recumbent. They remain in sternal recumbency in the initial phases and in the more advanced stages become laterally recumbent with evidence of respiratory failure.

35.81.4.5

CLINICAL COURSE

As with horses, the rate of progression of clinical signs in cattle after ingestion of toxin-contaminated forage is toxin dose dependent. Typically, cattle that absorb a moderate amount of botulinum toxin exhibit evidence of weakness 24 to 48 hours before becoming recumbent, then are unable to rise for 2 to 3 days before death.

Low toxin concentrations may not yield any clinical signs for 7 to 10 days or longer after toxin ingestion.[2316] Massive concentrations of toxin may lead to clinical signs within 12 to 24 hours of ingestion, but this is rare.

Animals with clinical evidence of botulism should have minimal physical activity. This includes not standing the animal up frequently or hauling in a truck long distance. Physical activity adversely affects the progression of clinical signs. Physically active cattle or cattle that are stimulated to walk some distance are more likely to be affected by lower doses of toxin. The physical activity results in depletion of acetylcholine reserves and may exacerbate muscle weakness, leading to recumbency within 12 to 24 hours, which results in a poorer prognosis for survival.

Most cattle that progress quickly to recumbency after botulinum toxin absorption die as a result of respiratory failure, dehydration, or other complications of recumbency. Cattle with a more gradual progression of clinical signs before becoming recumbent are often able to eat, drink, and swallow and may recover. Typically, down cattle affected with botulism that recover will be down for 5 to 10 days and then gradually regain sufficient muscular strength to rise again. In the author's experience, in a typical herd outbreak, many cattle will have subclinical signs, such as a weak tongue and decreased jaw tone, possibly mild dysphagia, and will never become recumbent. These animals should have a detectable antibody response to botulinum toxin 3 to 4 weeks after recovery from subclinical botulism.[2321–2324] The clinical course ranges from 2 to 30 days, depending on the dose of toxin absorbed and treatment provided. In cattle, 30% to 50% mortality rates are most common.

35.81.5 Other Large Animal Species

Type C botulism has been reported in bighorn sheep in California[2325] and in sheep in South Africa associated with feeding poultry litter.[2326,2327] The later report indicates the importance of sampling both the rumen and the cecal contents for botulinum toxin testing, because in this case the rumen samples were negative but the cecal contents were positive for preformed toxin.

35.81.6 Differential Diagnosis

35.81.6.1 DIAGNOSTIC RULE-OUTS FOR HORSES

Differential diagnoses for horses include any disease associated with muscular weakness and dysphagia, equine protozoal myelitis (EPM), rhinopneumonitis (spinal cord myeloencephalopathy),[2328] West Nile virus, white muscle disease, azoturia, eclampsia, guttural pouch mycosis, leukoencephalomalacia (moldy corn poisoning), eastern and western equine encephalitis, yew poisoning (*Taxus* species), rabies, white snakeroot poisoning, yellow star thistle toxicosis, hypocalcemia, organochlorine toxicosis, and pharyngeal ulceration. EPM with brainstem involvement is one of the most difficult diseases to differentiate from early botulism. However, most horses with EPM have asymmetric neurologic deficits, which rarely occur with botulism. Ionophorous antibiotics (monensin, salinomycin, narasin) may produce signs of profound muscular weakness similar to those seen in botulism, but dysphagia and the absence of increased muscle enzymes distinguish botulism. The absence of systemic signs of illness also helps the practitioner differentiate botulism from sepsis and more generalized infectious diseases.

Hyperkalemic periodic paralysis (HYPP) should be included in the diagnostic rule-out list for myasthenic quarter horses. HYPP, a dominant inheritable condition of quarter horses, is characterized by episodes of

muscular fasciculations, weakness, myotonia, and recumbency.[2329] These episodes are associated with hyperkalemia attributable to a defect in sodium channels. Electromyographic examination, plasma potassium, and demonstration of a DNA marker help confirm HYPP.[2330]

35.81.6.2 DIAGNOSTIC RULE-OUTS FOR CATTLE

Most herd outbreaks of botulism involve several cows at the same time in all stages of lactation. Hypokalemia and hypocalcemia resemble botulism but are easy to differentiate, because most cases of hypocalcemia occur in the periparturient period, and hypokalemia is most common in early lactation. Listeriosis almost always has localized cranial nerve involvement, which is not present with botulism cases. Organophosphate toxicosis results in sailosis, nervousness, and constricted pupils, not mydriasis as occurs with botulism. Spinal cord compressions, as may occur with lymphosarcoma or vertebral body abscess, are single-animal diseases and not herd problems.

35.81.7 Clinical Pathology and Diagnostic Approach

Laboratory support for a diagnosis of botulism requires one of the following: (1) demonstration of preformed toxin in the patient's serum or gastrointestinal (GI) contents or in a wound; (2) demonstration of *Clostridium botulinum* spores in the GI contents or feed materials, with compatible clinical signs; or (3) the detection of an antibody response to *C. botulinum* in patients recovering from suspected botulism. A definitive diagnosis may be obtained by demonstration of preformed toxin in plasma or GI contents, but this is rarely possible in adult horses. Preformed toxin has been identified in about 30% of GI contents of shaker foals, but rarely in adult horses. Finding botulinum spores in the intestinal or rumen contents, with clinical signs compatible with botulism, is strongly supportive of botulism because botulinum spores are rarely detectable in the rumen or GI contents of normal cattle or horses.

1099

1100

Botulinum toxin is relatively stable in tissues or plasma frozen at −20° C (−4° F) for several weeks. The mouse bioassay, the most sensitive test for botulism currently available, requires a minimum of 5 mL of plasma or serum from an affected animal as early in the clinical course as possible. Detection of toxin in the serum is likely only in animals with peracute onset and rapidly progressive clinical signs (onset to death in less than 48 hours). The serum (1 mL) is injected into two ICR Swiss Webster mice. If clinical signs of botulism occur in the mice (“wasp waist”), four additional mice are injected with the suspect serum. Two of the mice receive either a monovalent or a polyvalent botulism antiserum, depending on the history, along with the test serum. If mice are protected by a specific antitoxin, the test is definitive for the presence of botulinum toxin of that type.[2329] Unfortunately, because horses are very susceptible to botulinum toxin, the level of circulating toxin in an affected horse is often below the threshold of detection of the mouse bioassay. Few reports have demonstrated preformed toxin (type B) in plasma (or serum) from an acutely affected foal or horse.[2330,2331]

A tentative diagnosis may be based on the presence of botulinum spores and toxin in feedstuffs recently consumed by animals having clinical signs compatible with botulism.[2301] Spores of *C. botulinum* type B are found in the feces of approximately 34% of adult horses (three fecal samples per horse) with clinical signs compatible with botulism. *C. botulinum* toxin and spores can be found in the feces of approximately 20% and 70%, respectively, of foals affected with botulism. Spores are rarely detected in fecal samples from normal foals or adult horses.[2310] The presence of neutralizing botulinum antibody is a recently recognized indicator of botulism in nonvaccinated animals.[2321–2324] The polymerase chain reaction (PCR) for the detection of botulinum neurotoxin gene type B was reported to be more sensitive than the mouse bioassay in a natural case

of type B botulism in Australia.[2332,2333] At present, however, this technique remains a research tool that is not readily available for routine diagnostic purposes. In the author's experience, electromyographic evaluation has not been very rewarding to confirm a diagnosis of botulism in horses.[2301]

Typically, botulism is a diagnosis by exclusion, ruling out other diseases that may result in similar clinical signs. Both hematologic and routine plasma biochemical findings in early to moderate cases of botulism show few abnormalities. Hyperglycemia is often present[2334] and expected in cases of botulism, because elevated blood glucose is expected in many life-threatening diseases of cattle. If significant abnormalities are present, a disease other than botulism should be strongly considered. The gradual progression of clinical signs over 1 to 4 days, including dysphagia, decreased tongue tone, and muscular weakness leading to recumbency, is fully compatible with botulism.

35.81.8 Pathophysiology

Botulinum toxin acts primarily presynaptically at the peripheral cholinergic neuromuscular junction by blocking the evoked release of acetylcholine.[2268] The three steps involved in the neuromuscular blockage are (1) a primary step in which toxin heavy chain binds rapidly and irreversibly to receptors on the presynaptic nerve terminal, (2) an internalization process involving receptor-mediated endocytosis of the toxin light chain, and (3) a final blocking step to prevent the release of acetylcholine from the vesicle,[2272] leading to a flaccid paralysis. Once toxin is bound at the motor endplate, improved neuromuscular function is achieved only by the regeneration of new endplates; thus the prolonged time of a week to 10 days for clinical improvement after antitoxin therapy. Each neurotoxin serotype has its own specific receptor, an endopeptidase,[2335,2336] which may explain differences in species susceptibility to different toxin types. (For more detail about the neurotransmission, see Dasgupta.[2269])

Toxicoinfectious botulism occurs in foals and was initially reported as “shaker foal syndrome.” Foals may ingest botulinum spores with their food material as “normal” contaminants. The spores then produce toxin in vivo in the GI tract, resulting in neurologic disease.[2303,2304,2315] Toxin is detectable in the feces of approximately 30% of shaker foals, but only in the acute clinical phase of the condition.[2310] Normal intestinal flora of adult horses, humans, and other animals inhibit intraintestinal growth of botulism spores, limiting the occurrence of toxicoinfectious botulism to neonates.[2337] In human infants less than 6 months of age, *C. botulinum* may colonize the GI tract, which lacks competing microbial microflora. After their ingestion, botulism spores vegetate to produce botulinum toxin, which may be detectable in the stool for several weeks.[2338]

Most cases of type B equine botulism are associated with spores in the hay and rarely with commercial grain contaminated by decomposed animal carcasses. Commercial feeds (grains) are seldom proven to be the source of botulism toxin for horses. The origin of botulism affecting only one or two horses on a farm is often not identified. When several horses are involved, the source is typically found to be the forage, as in outbreaks in California (hay cubes),[2314] Ohio (contaminated wheat fed to work horses),[2295] North Carolina (baled alfalfa hay),[2309] England (big baled hay),[2330,2339] Sweden (big bale ensilage),[2340] and Australia (oaten chaff).[2341] Silage and hay contaminated with type B botulinum toxin and spores are the typical sources of exposure for horses.[2310] Hay stored in plastic bags or tubes has become a common factor in many outbreaks of botulism in the United States and England.[2342,2343]

Conditions of low acidity (pH >4.5), low oxygen, and high water content favor spore germination and toxin production. Small-grain forage, such as ryelage, oatlage, wheatlage, and barley,[2344] frequently provides these conditions and is a major risk factor for bovine botulism. The small-grain forages have a narrow window of harvest; if harvested too early or too late, fermentation is inadequate, and the pH remains high, helping botulism spores to vegetate, producing botulinum toxin. Spoiled hay or poorly fermented silage also represents potential sources of botulism exposure for horses.[2281] Silage with high pH (>4.5) is a well-known source of botulism for horses and is not a recommended equine feed because horses are much more susceptible to botulism toxin than cattle.[2301]

35.81.9 Necropsy Findings

Typically, no obvious gross or histologic lesions are associated with botulism in most species. Myositis or aspiration pneumonia may be present in some foals and adult horses because the deglutition reflex is abnormal. Patches of edema among the cervical muscles of an adult horse suggest type C botulism because some horses are unable to lift their head when affected with this toxin type.

35.81.10 Treatment and Prognosis

Equine botulism is usually fatal unless affected animals are promptly treated with specific antitoxin.[2310] In a series of 91 foals, yearlings, and adults with presumed type B botulism, none was treated with antitoxin and only two of the foals survived.[2345] On the other hand, a recent report of 30 foals affected with botulism had a survival rate of greater than 98% when treated with antitoxin.[2346] Neutralization of circulating toxin with a specific or multivalent botulinum antiserum should be the first and immediate therapeutic objective. Every hour between initial examination and antitoxin treatment results in a poorer prognosis for survival. Only one dose of antitoxin is needed because the half-life of botulinum antitoxin of equine origin is about 12 days in normal horses. Unfortunately, the antitoxin has no effect on the toxin after binding to the cell receptor; thus the importance of immediate treatment.[2269] Once an adult horse is recumbent, the prognosis for survival is greatly reduced, with less than 15% survival. Because the prognosis for survival in recumbent horses is poor, these animals should not be treated with antitoxin, unless the owners are fully appraised of the poor prognosis, the extensive nursing care that will be required, and the huge financial costs of an attempt to save these recumbent animals.

1100
1101

The recommended dose of antitoxin is 200 mL (30,000 IU) for a foal and 500 mL (70,000 IU) for an adult horse. A single dose of antitoxin should provide passive protection for more than 60 days. Horses with mild, slowly progressive disease may survive without antitoxin, as long as the patient is confined to a stall to restrict muscular activity as much as possible. Frequent attempts to force the horse to rise are also contraindicated to avoid further depletion of acetylcholine stores and exacerbation of the clinical signs. Antimicrobials may be given for specific secondary complications (e.g., aspiration pneumonia). If antimicrobials are used, those that may potentiate neuromuscular weakness should be avoided (e.g., aminoglycosides).[2347,2348] Metronidazole, often effective against anaerobic bacteria,[2349] is not effective against botulism and has predisposed laboratory animals and human patients to develop botulism.[2350] Mineral oil is often recommended as a cathartic for horses with ileus to prevent impaction colic. Parasympathomimetics (e.g., neostigmine) and 4-aminopyridine are countraindicated for the treatment of botulism in animals.[2310]

Most equine patients cannot swallow, so supportive alimentation is required. A high-quality protein slurry composed of 4 lb of alfalfa meal and up to 12 L of water should be administered twice daily by nasogastric tube using a bilge pump to support a 1000-lb horse. Hydration should be monitored by daily determinations of packed cell volume (PCV) and total plasma protein (TPP). Alfalfa meal gruel with adequate water was shown to maintain dysphagic horses for more than 2 weeks.[2313] Expensive mixtures of electrolytes and semipurified nutrients are not necessary for oral alimentation.[2351] If the horse or foal is recumbent, it should be fed in a sternal position and supported during gastric emptying. Recumbent foals are prone to developing ileus and may accumulate a large amount of fluid in their stomach, which must be relieved by nasogastric intubation. Additionally, recumbent male horses require bladder catheterization several times daily because they are unable or unwilling to urinate. If not catheterized, severe cystitis or bladder necrosis may result. Because most animals continue to attempt to eat, muzzling may be necessary to prevent aspiration of food or bedding, which can lead to aspiration pneumonia.

Foals often require intragastric feeding with either mare's milk, goat's milk, or a commercial milk replacer (Foal-Lac; Borden) through an indwelling nasogastric tube (Levin Tube, 16 Fr, 1.27 m; Davol). Additional therapy often includes histamine receptor (H_2) blockers such as ranitidine or cimetidine, along with sucralfate to help prevent gastric ulcers, which occur frequently in shaker foals.[2308] Ophthalmic lubricating ointments (Lacri-Lube; Allergan Pharmaceuticals) are often needed to prevent corneal abrasions that may result from decreased eyelid tone. Recumbent foals must be turned frequently to help prevent decubital ulcers and muscle necrosis. Parenteral antibiotics (e.g., potassium penicillin, ceftiofur sodium) are indicated to help reduce secondary infections, especially inhalation pneumonia. Approximately 50% of foals with botulism will require supplemental oxygen, and 30% will require mechanical ventilation.[2352] In foals requiring mechanical ventilation, 87.5% survived.[2352]

Recovery from botulism depends on toxin dose and the resulting severity of the clinical disease. Dysphagic horses that are able to stand will gradually regain the ability to swallow over 3 to 7 days. The more complete the dysphagia, the longer is the time required for recovery. An occasional horse will remain dysphagic for more than 2 weeks. Most adult horses are able to eat hay and swallow grain and water by 7 to 10 days after treatment with antitoxin. Return to full strength often takes more than 1 month. Very few adult horses that become recumbent and are unable to rise for 24 hours recover unless they are provided meticulous nursing care. Decubital ulcers and secondary respiratory problems are the major complications. Recumbent foals are usually able to stand after 7 to 10 days of intensive nursing care.[2308]

35.81.11 Prevention

A toxoid for *Clostridium botulinum* type B, BotVax B, is available from Neogen Corporation (Lexington, Ky). Three doses of vaccine 1 month apart are required to successfully immunize horses according to current recommendations.[2353] Alternatively, three vaccinations given at 10-day to 12-day intervals may provide protective antibody after 3 weeks, if necessary for emergency situations (e.g., outbreaks).[2354] Annual revaccination of pregnant mares 4 to 6 weeks before foaling is highly recommended. Horses from an endemic area should be revaccinated annually. The colostrum from vaccinated mares receiving boosters 6 to 8 weeks before foaling should contain adequate antibody to protect the foal for 8 to 12 weeks.[2355] Foals vaccinated with toxoid in the first few days of life should be immunoresponsive and should develop antibodies to the toxoid, even in the presence of passive antibody.[2354] Foals or weanlings given only two doses of toxoid may not be protected.

Botulism toxoid is considered highly efficacious when administered properly and is regarded as one of the safest and most effective vaccines for horses. Occurrence of clinical botulism in fully immunized horses has not been reported. No multivalent vaccine or licensed type C toxoid for horses is available in North America at this time. However, horses have been vaccinated and immunized with a type C toxoid approved for use in mink. This vaccine has been used for several years in endemic type C areas, such as southwestern United States.

35.82 POLYNEURITIS EQUI (NEURITIS OF CAUDA EQUINA; CAUDA EQUINA NEURITIS)

35.82.1 Definition and Etiology

The etiology of polyneuritis equi in horses is unknown. Inflammatory changes occur in various nerve roots, particularly those of the cauda equina and cranial nerves. All nerve roots may be affected to a greater or lesser degree, which has led to the use of the term *polyneuritis equi* as a more descriptive name for the condition than its previous name of "cauda equine neuritis."[2356–2358]

The disease usually occurs in adult horses,[2356–2361] although it has been described in a yearling filly.[2359] No breed or gender predilection has been noted.[2360]

Several hypotheses have been proposed for the cause of this disease. The lesions it causes bear some histopathologic resemblance to experimental allergic neuritis of rats, coonhound paralysis of dogs, and Guillain-Barré syndrome in humans, all of which are suspected of having an autoimmune basis.[2361,2362] Other proposed etiologies include a hypersensitivity reaction after systemic infection, aberrant migration of helminth larvae, and association with equine herpesvirus type 1 (EHV-1) and equine viral arteritis (EVA) infections.[2359,2360,2363–2365] However, conclusive evidence supporting any of these theories is lacking.

35.82.2 Clinical Signs and Differential Diagnosis

The clinical signs of polyneuritis equi reflect the involvement of the lower motoneurons and sensory neurons at the level of the nerve roots. In the initial stages of the acute form, horses show signs of hyperesthesia, particularly around the tailhead, and rub and chew at this area.[2361] Sometimes pain is apparent, and horses become apprehensive of handling.[2366] The condition can progress to hypoesthesia or anesthesia of the affected areas.[2356,2357,2363] In the chronic form a gradually progressive paresis of the tail, bladder, rectum, and anal sphincter develops, which may terminate in paralysis.

Common signs include weakness or paralysis of the tail.[2367,2368] The anus may be hypotonic or atonic and distended.[2356,2366–2369] Fecal retention or incontinence is sometimes a feature.[2356,2357,2363,2366,2370] Urinary incontinence occurs in many horses because of involvement of parasympathetic fibers in the sacral nerves and is the lower motoneuron type (i.e., bladder is atonic, distended, and easily expressed manually). In severe cases, overflow incontinence develops, and urine dribbling may cause vaginal hyperemia and scalding of the perineum in mares and scalding of the thighs in animals of either gender.[2356,2357,2363,2367–2371] Retention of urine predisposes to urinary tract infections.[2369] In males the penis may be relaxed and protruding, with decreased sensation in the perineal skin.[2356,2357,2369] Impotence resulting from incomplete erection and inability to achieve intromission was the presenting complaint in one stallion with polyneuritis equi.[2372] The preputial skin, which derives its innervation from spinal cord segments L2 to L4 through the genitofemoral

nerve, usually retains normal sensory function.[2373] When the nerve roots of the lumbosacral enlargement of the spinal cord are involved, hindlimb weakness with ataxia is seen.[2360,2361,2363,2366] Weakness and ataxia have been observed in all four limbs of some horses.[2357,2361,2367,2370] The gait may be stiff,[2366,2369] and denervation atrophy of muscles may result.[2366]

Cranial nerves can be involved. The signs depend on the individual nerves affected and the severity of the disease. The motor branch of the trigeminal nerve is reported to be most often involved, resulting in atrophy of the temporal and masseter muscles, with drooling and dysphagia.[2367,2370,2371,2374] Involvement of the facial nerve results in unilateral or bilateral facial paralysis, which can cause keratitis and corneal ulceration.[2361,2363,2367,2370,2374] Head tilt and other signs of cranial nerve dysfunction may also occur.[2357,2367,2374]

Any disorder that affects the cauda equina may cause similar signs. These include instabilities of the caudal spine caused by luxations or fractures, EHV myelitis, sorghum intoxication, and infectious diseases that involve the cauda equine, as well as some primary diseases of the lower urinary tract.[2375–2377]

35.82.3 Clinical Pathology

Cerebrospinal fluid (CSF) may have a mononuclear and neutrophilic pleocytosis, sometimes with more than 100 cells/μL.[2359] The CSF protein concentration usually is moderately to markedly increased.[2360,2370,2374] Electromyographic abnormalities occur in polyneuritis equi as a result of denervation of affected muscles. A recent study suggests that the presence of circulating antibodies to P2 myelin protein may prove to be a useful diagnostic test, but further research is required to confirm this.[2378,2379]

35.82.4 Pathophysiology

The finding that some horses with polyneuritis equi possess antibodies to P2 myelin protein supports the theory that this disease has an autoimmune etiology.[2378,2379] An initial traumatic or infectious insult might cause the release of autoantigens from nerve tissue and disrupt the blood-nerve barrier so as to permit an autoimmune reaction.[2366] Experimental inoculation of P2 protein in rats produces an antibody response and an allergic neuritis that shares some pathologic features with polyneuritis equi.[2380] However, such autoantibodies may represent an epiphenomenon and may not be central to the pathogenesis of the disease.

35.82.5 Necropsy Findings

The main lesions are in the nervous system. The cauda equina is thickened, discolored, and covered with edematous tissue and fibrous material.[2361,2371,2381] There may be adhesions of the nerve roots or the spinal cord to the meninges and the periosteum of the vertebral canal.[2356,2369] Subdural or epidural petechiation and hemorrhage are sometimes seen.[2356,2363,2366]

At the microscopic level the major finding is a granulomatous inflammation that is most intense in the extradural part of the nerve roots. On rare occasions, microabscesses are found at the center of the granulomatous lesions.[2356,2361] The epineuria, perineuria, and endoneuria are thickened and are infiltrated to varying degrees by lymphocytes, plasma cells, lymphoblasts, macrophages, giant cells, eosinophils, and in rare cases, neutrophils.[*] Intraneural inflammation, necrosis, and endoneurial thickening can obliterate nerves.

2356,2363,2366 Axonal degeneration and demyelination are present.2361 Often, myelinated axons are absent in the affected nerves. Mildly affected nerves have axonal swelling and ballooning of myelin sheaths. Nerve bundles are separated by large amounts of fibrous tissue. There is minimum to moderate evidence of nerve regeneration. 2361

Lesions can also be found in the spinal cord itself, having occurred secondary to the nerve root lesions, such as wallerian degeneration in the dorsal columns and axonal reaction in the ventral horn cells.2366 Inflammatory lesions in dorsal root ganglia and in trigeminal ganglia have been found in some horses with this disease.2367

* References 2356, 2361, 2363, 2367, 2368, 2371.

35.82.6 Treatment and Prognosis

Treatment with corticosteroids at antiinflammatory doses early in the course of the disease may be helpful. 2359,2363,2371,2382 However, no therapy has consistently been shown to be effective. Immunosuppressive drugs, such as azathioprine, may be useful in the treatment of polyneuritis equi, but their use for this disease has not been reported.2383 General supportive care should be given, including fluid therapy when necessary, and the bladder and bowels should be manually evacuated. Because of the slow progression of signs in some horses, these animals may be maintained on supportive care for a long time. Because of the severity of the clinical signs, the gradual deterioration, and the poor prognosis, euthanasia usually is the eventual choice.

1103

35.83 *SORGHUM* TOXICITY

35.83.1 Definition and Etiology

A syndrome of ataxia and cystitis in horses, cattle, and sheep has been linked to the feeding of *Sorghum* species.2384–2389 The underlying mechanism is probably toxic damage to the central nervous system, but the precise toxin responsible is not known. This disease does not appear to be linked to the breed, gender, or age of an animal.2385

35.83.2 Clinical Signs

The first sign observed usually is ataxia of the hindlimbs, usually followed by urinary incontinence. Affected animals have a swaying hindlimb gait and a tendency to knuckle over. Occasionally, affected horses may walk with a hopping gait, in which both hindlimbs are lifted off the ground simultaneously (Fig. 35-48). Signs in horses tend to worsen on backing, and animals may fall or even become recumbent.2385 During an outbreak of the disease in cattle, 3 of 54 affected cows became recumbent, and two of these died.2386 The perineal muscles are relaxed, and urine dribbles from a flaccid, distended bladder.2385,2386 In mares the vulva opens and closes repeatedly; in stallions and geldings the penis is relaxed and protrudes from the prepuce.2385 Paresis of the tail may be present in both horses and cattle. Loss of skin sensation over the hindquarters has been described in a cow, suggesting involvement of both sensory and motor nervous pathways.2386 Head shaking, ataxia, weakness, recumbency, opisthotonos, and death have been reported in sheep, and mortality can approach 50%. 2384

Cystitis in affected animals may be severe and occurs secondary to urine retention. Dribbling of urine onto the skin of the perineum and hindlimbs results in scalding of the skin and dermatitis. Pyelonephritis is a common sequela to chronic cystitis and may be fatal.[2385,2387] Sometimes the clinical signs may be chronic; in one outbreak, horses had been showing signs for as long as 3 years.[2385]

Abortion in mares, arthrogryposis as a congenital deformity of foals and lambs, and neurologic abnormalities in newborn lambs also have been linked to the feeding of *Sorghum* plants.[2384,2385]

35.83.3

Clinical Pathology

Diagnosis of sorghum toxicity is made by the presence of typical clinical signs in association with a history of feeding *Sorghum* plants. No specific diagnostic test is available. Cystitis and pyelonephritis are identified by typical findings on routine urinalysis, serum biochemistry, and urine culture.

Fig. 35-48 Characteristic “rabbit hopping” gait of a horse with lathyrism. This horse was believed to have eaten sweet peas (*Lathyrus* species). Horses may also simply show ataxia and paraparesis. Courtesy Dr. G.P. Carlson.

35.83.4 Pathophysiology

The precise nature of the toxic substance in *Sorghum* plants that causes this syndrome is unknown. Most *Sorghum* species are cyanogenetic plants that contain hydrocyanic acid at potentially toxic concentrations.[2389] Chronic exposure to cyanide has been suggested as the cause of the neuropathologic changes found in affected animals.[2385] Similarities in the clinical signs of this syndrome and those of neurolathyrism in humans have led to the suggestion that the toxic principle in *Sorghum* plants may be a lathyrogen-like substance.[2390]

35.83.5 Epidemiology

The cyanide content of *Sorghum* plants is increased by drought or freezing and also is higher in new shoots and wet plants.[2389,2390] In one survey of the disease in horses, most cases occurred during the wet season and involved young, growing plants.[2385] The period of grazing before the onset of signs ranges from 1 week to many months.[2385,2386]

35.83.6 Necropsy Findings

Wallerian degeneration, swelling of axons and myelin sheaths, and demyelination in a small number of nerve fibers throughout the length of the spinal cord, in the cerebellum, cerebellar peduncles, and the pons have all been described, together with the presence of phagocytic gitter cells.[2384–2386] These changes are not associated with specific tracts.[2386] Ultrastructural studies of brains and spinal cords of affected sheep have revealed that the axonal swelling (spheroids) are composed of aggregates of neurofilaments, mitochondria, vesicular bodies, and dense bodies, enclosed within a thin myelin sheath.[2384]

35.83.7 Treatment and Prognosis

Withdrawal of *Sorghum* plants from the diet of affected animals results in a gradual improvement in the clinical signs over weeks to months, although recovery may not be complete.[2384,2386] Death is a potential sequela, however, and mortality can be high in some cases.[2384] There is no specific treatment for affected animals. Supportive therapy includes antibiotics for treatment of bacterial urinary tract infections.

35.83.8 Control

Avoidance of feeding *Sorghum* plants as a predominant part of the diet or the sole diet is the only method of control. This plant has considerable feed value and should not present a major hazard when used as part of a diversified feeding regimen.

35.84 STRINGHALT (SPRINGHALT; HAHNENTRITT)

35.84.1 Definition and Etiology

Stringhalt is a disorder of unknown etiology that produces a characteristic hyperflexion of one or both hock joints in affected horses. The sporadic form usually affects a single hindlimb and is often associated with traumatic injury, although in some cases no inciting cause is identified. The epidemic form affects both hindlimbs and sometimes the forelimbs. This form also is called *bilateral stringhalt,* rather than "epidemic" stringhalt. Laryngeal paresis from involvement of the recurrent laryngeal nerves also has been described in this form of the disease. This form of stringhalt occurs often as an outbreak in groups of horses grazing poor-quality, weed-infested pastures; it is suspected to have a toxic etiology.

35.84.2 Clinical Signs

Affected horses appear normal at rest but have a characteristic involuntary hyperflexion of the tarsocrural joint when moving. The disorder may be unilateral or bilateral and can vary in severity from a slight exaggeration of normal movement to a motion wherein the rear foot strikes the belly. A grading system has been proposed, with the severity of signs classified from grade I to grade V.[2391] In grade I, mild signs are noted just as the horse begins to move; in grade V, animals are reluctant to move and have a "bunny-hopping" gait when forced to do so. The signs generally worsen on turning or backing and may also be more severe when the animal is frightened, after a period of rest, or in cold weather.[2392–2394] Knuckling of the forelimbs may occur in the epidemic form of the disease, sometimes with evidence of laryngeal weakness in the form of dyspnea or "roaring." Atrophy of muscles in the affected limbs is usually a feature of stringhalt and is most severe in distal limb muscles.

1103 1104

35.84.3 Clinical Pathology

No abnormal clinical pathologic findings are associated with stringhalt. Electromyography of affected muscles reveals increased insertion activity and abnormal spontaneous activity, such as fibrillation potentials and positive sharp waves, consistent with denervation.[2395,2396] Nerve conduction velocity is slowed in the peroneal nerves of affected limbs, indicating demyelination, and improves as animals recover clinically.[2391]

35.84.4 Pathophysiology

The etiology and pathophysiology of stringhalt are unknown. The sporadic form occurs in individual animals. In some sporadic cases, a history of traumatic injury to the limb, particularly to the dorsoproximal metatarsus, precedes the development of stringhalt by several months,[2397,2398] although in other cases the cause is unknown. Explanations for the development of stringhalt after traumatic injury include tendinous adhesions and alterations in the function of nervous or muscular components of the myotactic reflex in the affected muscles.[2393,2399,2400] Outbreaks of stringhalt among horses in Australia and the United States have been associated with ingestion of certain plants, particularly *Hypochoeris radicata* (catsear), but a causal role for a plant toxin has not been proved experimentally.[2401–2403] Other related plants that have been associated with the development of stringhalt include *Taraxacum officinale* (dandelion) and *Malva parviflora* (cheeseweed mallow).[2394] Lathyrism, a toxicity caused by plants of the *Lathyrus* (flatpea) family, can cause signs similar to stringhalt (see

earlier discussion). Detailed pathologic studies of horses affected by the epidemic form of stringhalt have revealed that the lesion is a distal axonopathy in peripheral nerves that selectively affects large-diameter myelinated axons.[2402,2404] The pathologic changes are widespread and involve nerves of the forelimb and the recurrent laryngeal nerves, as well as those supplying the hindlimbs. Neurogenic myofiber atrophy is present in muscles innervated by the affected nerves, with type II fibers being more severely affected than type I fibers. Recovery in affected horses is presumed to result from axonal regeneration, a process that requires an intact neuronal cell body.[2402]

35.84.5 Epidemiology

The sporadic form of stringhalt occurs in individual animals worldwide and at any time of year. The epidemic form occurs in outbreaks in which several horses in the same location are affected; it has a seasonal incidence, being most prevalent in the late summer or early autumn after a period of very dry weather. Outbreaks have been reported in Australia (thus the alternative name for the epidemic form, “Australian stringhalt”) and in the western United States.[2405,2406]

35.84.6 Necropsy Findings

Lesions are limited to the peripheral nerves and muscles.[2402] There is a loss of large-diameter myelinated fibers in a number of peripheral nerves, especially those innervating the hindlimbs and the recurrent laryngeal nerves. The pathologic changes in the nerves include demyelination, fibrosis, and proliferation of Schwann cells. Longer nerves are more severely affected. Muscles innervated by the affected nerves show evidence of denervation atrophy, particularly of type II myofibers.

35.84.7 Treatment and Prognosis

Individual cases rarely recover spontaneously. Surgical therapy by tenotomy or tenectomy of the lateral digital extensor tendon has been the treatment of choice in sporadic cases, resulting in a guarded to favorable prognosis for recovery.[2392,2393,2407] Conservative treatment using gradually increasing exercise or intraarticular administration of corticosteroids also has been advocated for animals with a history of trauma to the affected limb.[2397,2398] One study found no apparent significant difference in outcome between horses that underwent surgery and those managed conservatively.[2397] Steroid therapy was successful in the one case reported, whereas exercise alone resulted in improvement in two of four horses but complete recovery in only one horse.[2397]

In the epidemic form, most horses recover in weeks to months without treatment.[2401] Because a toxic etiology is suspected, it is usually recommended that the horses be removed from the pasture they were grazing when they developed signs. Administration of phenytoin (10 to 15 mg/kg orally once or twice daily) resulted in clinical improvement and reduced abnormal electromyographic activity within 24 hours of starting therapy and reached full effect by 1 week.[2396,2408] Horses that did not recover spontaneously while receiving phenytoin showed reappearance of signs within a few days. Mild sedation is a possible side effect of this treatment. Other drugs reported to have variable beneficial effects include mephenesin and baclofen.[2409–2411]

35.84.8 Control

Because plant toxicity is suspected as the cause of the epidemic form of stringhalt, control is best effected by not grazing horses on weed-infested pasture and by using weed control and good pasture management where horses are being grazed. Judicious exercise regimens may be helpful in reducing the likelihood of stringhalt in horses that have sustained traumatic injuries to the dorsoproximal region of the metatarsus.[2397]

35.85 TICK PARALYSIS

35.85.1 Definition and Etiology

An ascending lower motoneuron paralysis has been described in horses, sheep, cattle, and goats in Australia, associated with infestation by the tick *Ixodes holocyclus*.[2412–2417] In the United States a similar disease occurs in dogs, humans, cattle, New World camelids, and wild animal species as a result of infestation with several *Dermacentor* species.[2418,2419] A similar problem occurs in small ruminants in Africa, where *Ixodes rubicundus* and *Rhipicephalus evertsi evertsi* are the tick species implicated.[2420]

35.85.2 Clinical Signs

Progressive generalized paresis develops over one to several days, terminating in recumbency. Death from respiratory paralysis may occur in as little as 24 hours in severe cases.[2412] Animals may be found recumbent or may be paraparetic and ataxic in the early stages of disease. When signs are mild to moderate, differential diagnoses include a variety of neurologic and nonneurologic diseases, such as rabies, colic, uterine torsion, trauma, myelopathies, myopathies, and metabolic disorders. These do not usually progress to the profound muscular flaccidity seen in tick paralysis.[2421] Reflex withdrawal from a noxious stimulus and the blink reflex both are reduced to absent, although sensory function appears normal. The major differential diagnosis for fully developed tick paralysis is botulism. Tick paralysis often is fatal when caused by *I. holocyclus,* but animals affected by *Dermacentor* species recover if the ticks are removed before the animals are moribund. Diagnosis is made on the basis of the clinical signs and finding ticks on the affected animal.

1104 1105

35.85.3 Clinical Pathology

There are no pathognomonic findings in affected animals except for the presence of ticks on the patient. Electromyography in tick paralysis in dogs in North America reveals minimal spontaneous activity and lack of evoked compound muscle action potentials in response to motor nerve stimulation.[2422] Findings in large animals can be expected to be similar. Cerebrospinal fluid is normal in tick paralysis, helping to differentiate it from some, but not all, myelopathies.

35.85.4 Pathophysiology

The cause of tick paralysis is believed to be a neurotoxin in the saliva of female ticks that is inoculated into the host when the tick feeds. Nymphs and larvae also may cause the disease.[2413,2415,2416] In the case of *I. holocyclus* the toxin has been named holocyclotoxin. The toxin elaborated by *Dermacentor* species has been

less well characterized. The pathogenesis of the disease is blockage of transmission at the neuromuscular junction as a result of reduced release of acetylcholine. Mortality is common in tick paralysis caused by *I. holocyclus* despite tick removal.

35.85.5 Epidemiology

The disease occurs worldwide, associated with different tick species in different areas. In North America the region from the Pacific coastal range to the Continental Divide provides especially favorable conditions for the proliferation of *Dermacentor andersoni*.[2418] Tick paralysis in the United States and Canada occurs mainly in the Pacific Northwest and the Rocky Mountains, although the range of the tick species involved covers a much wider area.[2421] The disease tends to be seasonal in North America, with most cases occurring in the spring, when ticks are most active. Smaller animals, such as sheep and New World camelids, are more often affected than cattle, probably because they receive a larger dose of the tick neurotoxin relative to their body size.[2421] Tick factors probably influence disease severity, and genetic variation within *I. holocyclus* may play a role in toxin potency.[2423] A short-lived immunity has been demonstrated in dogs exposed to ticks. Tick paralysis is most common in the early part of the season and in younger animals, suggesting that a similar phenomenon may occur in other species.[2421] The significance of host immunity is supported further by the finding that *D. andersoni* has reduced virulence in hamsters after the ticks are prefed on cattle previously exposed to the same species of tick compared with ticks prefed on naive cattle.[2424]

35.85.6 Necropsy Findings

There are no pathognomonic findings at necropsy, although the presence of ticks should increase suspicion of this disease. Death usually results from respiratory paralysis.

35.85.7 Treatment and Prognosis

Treatment is symptomatic after removal of the ticks, which is essential. Lack of improvement suggests that ticks remain on the animal, except in cases of *I. holocyclus* infestation, where signs persist and may worsen despite removal of all ticks. Spraying or dipping affected animals facilitates tick removal. In small animals, shaving the hair coat may be necessary to ensure detection and removal of all ticks. Areas such as the axillae and groin, in particular, provide good sites of attachment for ticks. The prognosis is good in the case of *Dermacentor*-induced paralysis when tick removal and supportive care are instituted before animals are moribund. Fatalities occur frequently in the case of *Ixodes*-induced paralysis despite removal of ticks. Cooling of the patient has been suggested in treatment of *I. holocyclus* toxicity because anecdotal clinical reports suggest that patients may be more likely to survive when cool. In vitro studies revealed that binding of holocyclotoxin at the neuromuscular junction is reduced in a cooler environment.[2425] However, such an approach may increase risk of severe complications in patients that are paralysed and cannot thermoregulate. A better approach may be to avoid warming the patient excessively.

Administration of hyperimmune serum has been shown to be beneficial in the treatment and prevention of this disease in dogs and in one llama.[2417,2426] Adverse reactions such as anaphylaxis, bradycardia, and hypotension occur in a small number of dogs and cats treated with hyperimmune serum, but these can be avoided by premedication of atropine.[2427] No report of such treatment in other species was found.

35.85.8 Control

Environmental control to reduce tick populations and routine use of acaricides may decrease the incidence of tick paralysis.

35.86 EQUINE DYSAUTONOMIA (GRASS SICKNESS)

Equine dysautonomia, commonly known as grass sickness, is a disorder of unknown etiology that occurs in horses, ponies, and donkeys in Great Britain and northern Europe.[2428–2434] A disease with similar clinical signs ("mal seco") has been described in horses in Colombia.[2435] The major clinical finding is a decrease in or cessation of gut motility. The signs of grass sickness, which are mainly caused by intestinal stasis, include colic, bloat, constipation, inappetence, weight loss, and dehydration. Esophageal dysfunction may be manifested by dysphagia. Paralysis of the urinary bladder occurs in some animals, and in males the relaxed penis may protrude from the prepuce. Significant cardiac functional disturbance has been documented in horses with grass sickness.[2436] The course of the disease varies from peracute with sudden death to chronic; some animals survive for many months despite alimentary dysfunction.[2429,2430,2437] Survival and return to function has been documented in horses midly affected with the chronic form of disease when they received good nursing care.[2437–2441] Risk factors for developing the disease include younger age, male gender, and location on premises that have previously experienced the disease. Dry weather has been identified as a risk factor, but not all studies support meteorologic influences on disease occurrence.[2442] Peak incidence occurs from April to June.[2443]

Histologic examination reveals characteristic degenerative changes in peripheral autonomic ganglia, in the myenteric and submucous plexuses, cardiac ganglia, and in certain central nervous system nuclei, particularly in the medulla oblongata.[2431,2432,2436,2444,2445] A reduction in the number of interstitial cells of Cajal within the gut wall has been demonstrated; these cells are believed to have a "pacemaker" activity, and their depletion may be central to the clinical manifestations of equine dysautonomia.[2446] Furthermore, electrical activity in the gut is decreased in grass sickness, possibly including that of the interstitial cells of Cajal.[2447] Studies of animals that recovered from the disease indicate that the histopathologic changes may be reversible.[2439] Some degree of esophageal dysfunction occurs in all horses with grass sickness.[2434] The histopathology of autonomic ganglia in horses that showed complete clinical recovery from grass sickness was virtually normal, with normal morphology in all four horses studied and normal cells numbers in three of the four horses.[2444]

1105 1106

Diagnosis rests mainly on clinical presentation; there are no definitive clinicopathologic abnormalities in grass sickness.[2448,2449] A small study demonstrated that the presence of chromatolytic neurons in rectal biopsies might be a useful adjunctive test for diagnosis.[2450]

Evidence for pathology not related to the gastrointestinal (GI) tract was found in a study of motor nerves and skeletal muscle in horses with grass sickness. The investigators found electromyographic evidence of a subtle peripheral neuropathy, which was further supported by mild pathologic changes in both muscle and nerve at necropsy.[2451]

There is mounting evidence for an association between equine dysautonomia and *Clostridium perfringens* type C neurotoxin.[2429,2452–2454] The presence of a neurotoxic factor in the plasma of affected horses was suggested by induction of typical neuropathologic lesions in ponies by intraperitoneal inoculation of plasma and serum from

horses with acute disease. Clinical illness was not observed in the ponies.[2455] Circulating antibodies to *C. perfringens* type C endotoxin have been positively associated with the development of grass sickness.[2456] Growth of the organism in the GI tract (toxicoinfection) is hypothesized to be the source of the botulinum toxin. On the other hand, horses with grass sickness have lower circulating levels of antibodies directed against the surface antigens of clostridia, suggesting that these may have a protective effect against the disease.[2457] This finding also raises the possibility of a vaccine against grass sickness. The number of bacteria, including clostridial species, is significantly increased in the intestines of horses with grass sickness, posing the question as to whether change in GI flora is a cause or a consequence of the disease.[2458]

Treatment of equine dysautonomia is supportive and includes supplementary feeding and fluid therapy. The indirect-acting cholinergic cisapride (0.5 to 0.8 mg/kg orally every 8 hours for 1 week) facilitates release of acetylcholine from the myenteric plexus and increases gut motility in chronic grass sickness. Colic signs may increase shortly after administration of this drug.[2459] Many affected animals die, but recovery has been reported in some chronic cases, as well as in 50% to 70% of chronically affected horses that receive appropriate treatment.[2431] Analgesia with intravenous flunixin meglumine or intravenous or oral phenylbutazone is appropriate in some cases, and diazepam (0.05 mg/kg every 2 hours) may be helpful as an appetite stimulant. Factors associated with a better prognosis include willingness to eat concentrates and milder signs of dysphagia.[2460]

35.87 PERIPHERAL NERVE DISORDERS

LISLE W. GEORGE

Most peripheral nerve disorders of large animals are traumatically induced, but injections, abscesses, tumors, and parasitic invasion of the nerves may occur in rare cases. The following section discusses the peripheral nerves most often damaged in large animals.

35.88 PERIPHERAL NERVES

35.88.1 Suprascapular Nerve

Mechanical damage to the suprascapular nerve results in paralysis of the infraspinatus and supraspinatus muscles.[2461] Early denervation is characterized by a slight outward bowing of the scapulohumeral joint as weight is placed on the limb. Neurogenic atrophy develops after several months, and the scapular spine becomes prominent (Fig. 35-49). The common name for this condition is “Sweeney.”

35.88.2 Brachial Plexus

Damage to the brachial plexus may result in any combination of dysfunction of the biceps and coracobrachialis muscles (musculocutaneous nerve), as well as the pectoral, subscapularis, and triceps muscles.

Lesions of the brachial plexus are caused by trauma to the shoulder, deep penetrating axillary wounds, or traction on the forelimbs of a fetus during relief of a dystocia. Because of their tendency to rear and jump over objects, horses are most susceptible to brachial plexus injuries. The condition may occur in small ruminants after automobile accidents, carnivore attacks, or blows from larger animals.

35.88.2.1

MOTOR DEFICITS

Severe lesions of the brachial plexus result in complete flaccidity of the forelimb. The animals are unable to bear weight. Triceps reflexes are absent. Loss of pectoral nerve function results in abduction of the elbow. Subscapular muscle paralysis results in dropped shoulder.[2462] Musculocutaneous nerve paralysis results in a hyperextension of the elbow at rest and an inability to flex the joint. There is loss of the biceps reflex. The clinical signs of radial nerve paralysis are described next.

35.88.2.2

SENSORY DEFICITS

Avulsions of the brachial plexus result in complete desensitization of the entire forelimb.

Fig. 35-49 "Sweeney" (neurogenic atrophy) of the left supraspinatus and infraspinatus muscles in a Charolais bull. The lesion was caused by trauma related to running through a cattle chute.

1106

35.88.3 Radial Nerve

The radial nerve is motor to the extensor muscles of the forelimbs. The nerve courses over the lateral aspect of the elbow joint and is vulnerable to traumatic insult at that point. Radial nerve paralysis most often arises from direct trauma to the nerve, during prolonged anesthesia, or during restraint in lateral recumbency with inadequate padding of the forelimb.[2463,2464] Degeneration of the triceps muscles also plays a significant role in many cases of radial nerve paralysis.[2463]

The limb position varies, depending on the location of the lesion in the radial nerve. Lesions at or near the elbow joint result in high radial nerve paralysis, characterized by a dropped elbow, failure of limb protraction with scuffing of the toe, and flexion of all distal limb joints (Fig. 35-50). The foot is knuckled over at rest, and the animal is unable to bear weight on the leg. Lesions of the distal radial nerve result in knuckling of the carpus, fetlock, and pastern joints. The animal can support weight on the affected limb if the metacarpus and distal limb are held in extension. The triceps reflex is depressed to absent. Chronic dysfunction of the radial nerve results in neurogenic atrophy of the extensor muscles of the forelimb. Detectable sensory deficits resulting from radial nerve paralysis tend to be vague and probably vary from patient to patient.

35.88.3.1 “KANGAROO GAIT” IN SHEEP

A bilateral forelimb locomotor disorder of pregnant and lactating female sheep has been reported in Scotland and northern England.[2465] The problem appears to be a bilateral radial paresis and is strongly associated with pregnancy and lactation.[2466] Sheep recover after weaning their lambs or even while still lactating. Sheep kept in lowland areas are more frequently affected than those in hilly areas, although it is unclear whether this results from environmental factors or differing susceptibilities inherent to the different breeds of sheep kept in these areas. Most sheep affected are outdoors grazing, and sheep that are housed, even for part of the day, are less likely to be affected. “Kangaroo gait” occurs most often in the late winter and early spring, when the greatest numbers of sheep are in late pregnancy and early lactation. There is no specific treatment, and most animals recover uneventfully, although signs may recur at later pregnancies. The most common differential diagnosis is lameness caused by the numerous orthopedic conditions of sheep.

Fig. 35-50 High radial nerve paralysis in a horse showing knuckling of the carpus and digit and dropped elbow. Courtesy Dr. R.H. Whitlock.

35.88.4 Femoral Nerve

The femoral nerve is distributed to the quadriceps femoris muscles and the skin of the rear limb extending from the medial thigh to the medial part of the coronet (saphenous nerve). Traumatic overextension of the hip and stifle joint from a fall or other injury or forced posterior delivery can damage the femoral nerve. The clinical signs of femoral nerve paralysis are related to an inability to extend and fix the stifle.[2461] The reciprocal apparatus is unable to fix the hock, resulting in collapse of the limb during weight bearing and constant flexion of all distal digital joints. Chronic lesions of the femoral nerve result in atrophy of the quadriceps femoris muscles and the muscles of the posterior part of the gluteals. The patellar reflex is absent or depressed, and the patella often is displaced laterally. There is analgesia to anesthesia of the medial part of the rear limb extending from the proximal thigh to the medial malleolus of the tibia.

35.88.5 Sciatic Nerve

The sciatic nerve innervates the extensor muscles of the hip, the flexor muscles of the stifle, and most of the muscles of the distal limb.

Sciatic nerve paralysis occurs most often in postpartum cows after forced fetal extraction. Loss of function of the lumbar branches of the nerve most likely plays a major role in the so-called calving or obturator paralysis syndrome.[2467] Injection of irritating drugs into the space between the greater trochanter and the ischial tuberosity may cause a sciatic neuritis. This occurs most frequently in neonates but can occur rarely in adult cattle and small ruminants. Other causes of sciatic nerve damage are pelvic fractures, tumors, or abscesses located along the course of the nerve.

The sciatic nerve innervates most of the musculature of the rear limb, so the motor deficits associated with denervation are profound. At rest the limb is hanging behind the animal. The stifle is dropped and extended (Fig. 35-51). The foot is constantly knuckled. If the limb is positioned properly, the animal usually can bear weight for a limited period because of the normal function of the quadriceps muscles and the action of the reciprocal apparatus. Chronic denervation of the sciatic nerve results in neurogenic atrophy of the caudal thigh muscles and all of the muscles distal to the stifle.

Fig. 35-51 Characteristic posture of a cow with partial sciatic nerve paralysis. The condition pictured here was induced during correction of a severe dystocia. Note the flexion of the hocks, fetlocks, and stifle. These signs differentiate the condition from peroneal paralysis. Courtesy Dr. R.H. Whitlock.

The sciatic nerve divides into the tibial and the peroneal nerves in the distal limb. Therefore, except for the medial part of the thigh and rear limb, there is analgesia and anesthesia of the entire limb distal to the stifle.

35.88.6 Peroneal Nerve

The peroneal branch of the sciatic nerve is distributed to the flexor muscles of the hock joint and the extensor muscles of the digit. The nerve becomes superficial and is exposed to damage as it crosses over the lateral condyle of the fibula.[2468] The condition is typically seen in all species of large animals and is common in postpartum dairy cattle that have been recumbent as a result of hypocalcemia or other causes and in horses because of postanesthetic myopathy. Neurologic deficits of the peroneal nerve result in a hyperextended hock joint and flexion of the fetlock and pastern[2461,2468,2469] (Fig. 35-52). Many cows knuckle at the fetlock even when the foot is flat on the ground, and others may be able to bear weight only when the limb is manually placed in the proper position.

There is desensitization of the skin over the craniolateral aspect of the limb extending from the stifle to the hoof.

35.88.7 Tibial Nerve

The tibial nerve supplies the extensor muscles of the hock joint (gastrocnemius) and the digital flexors.

Tibial paralysis is most often observed in periparturient cattle or neonates that have been given an injection of an irritant drug in the caudal leg at the level of the stifle. Tibial paralysis also is seen in sheep and goats and is a common sequela to dog-bite injuries. With tibial paralysis, the hock is overflexed and is pulled higher than normal when the limb is protracted. The toe does not drag on the ground, and the limb is dropped suddenly perpendicular to the ground at the end of the stride. At rest the pelvis is asymmetric, with the affected side held lower than normal.[2461] Chronic loss of tibial nerve function results in atrophy of the gastrocnemius and digital flexor muscles. There is anesthesia to analgesia of the skin of the caudomedial aspect of the leg.

Fig. 35-52 Calf with peroneal nerve paralysis. Note the flexed fetlock and digit and the hyperextended carpus. This condition was caused by injection of antibiotics into the peroneal nerve on the caudolateral aspect of the leg. Courtesy Dr. R.H. Whitlock.

35.88.8 Obturator Nerve

The obturator nerve supplies motor impulses to the adductor muscles. The nerve is well protected in the equine and small ruminants, and therefore damage is rare in these species. The cow has a shallow acetabulum and a poorly developed round ligament. Consequently, the condition is often seen in peripartum cows. Reports of obturator nerve paralysis of cattle accompanied by knuckling and inability to support weight on the rear limbs probably represent a combination of sciatic and obturator nerve deficits. Coxofemoral luxation is a common complication of obturator paralysis in cattle housed in stalls with slippery flooring. Such luxation can be recognized by the identification of crepitus during passive manipulation of the hip joint. There may be a difference in the length of the rear limbs.

Obturator nerve paralysis is most common in cattle and is almost always a result of dystocia. The nerve injury is located in the pelvis at the level of the obturator foramen. Of all dystocias, 9.2% result in paraplegia.[2470]

The obturator nerve innervates the adductor, pectineus, and gracilis muscles. Only minimum deficits are observed if the cow is placed on a surface that has good traction. Clinical signs of an obturator nerve deficit include a hopping gait when the animal attempts to run and severe abduction or splay-leggedness when the animal is placed on a slippery surface (Fig. 35-53). In severe cases the cow may be sternally recumbent with the rear limbs extending laterally to each side. Experimental studies have indicated that the so-called calving paralysis syndrome is actually a result of a combination of lesions of the lumbar root (L6) of the sciatic nerve and the obturator nerve. Experimental sectioning of the obturator nerve alone does not produce paralysis, provided the animal has a nonslip footing.[2461,2467,2471] Obturator nerve paralysis does not result in a cutaneous sensory deficit.

Fig. 35-53 Cow with obturator nerve paralysis caused by relief of a difficult dystocia. Note the base-wide stance, yet the apparent ease with which the cow is able to stand on the deep bedding. Note also that rope hobbles are being applied to prevent further abduction and possible luxation of the coxofemoral joint.

Damage of one or more peripheral nerves during parturition or milk fever may play a large role in the so-called downer cow syndrome (see later discussion).[2472,2473] The incidence of the condition ranges from 4% to 28% of all cases of milk fever and is associated with a mortality rate ranging from 20% to 67%.[2474–2477]

35.89 PERIPHERAL FACIAL NERVE PARALYSIS

The facial nerve becomes superficial as it courses across the lateral aspect of the mandibular ramus and the masseter muscle. It is most susceptible to blunt trauma or laceration at that site. Horses are most often injured from prolonged recumbency or from trauma caused by a poorly designed halter. Halters with large brass rings in the caudodorsal aspect of the cheek pouch are most likely to result in iatrogenic facial palsy. Similar conditions occur in goats and are caused by excessive pull on neck chains while the animal is being led onto the milk stand or tied with the neck chain. In cattle, facial nerve deficits usually are the result of space-occupying masses at the caudal aspect of the mandibular ramus.

Most animals with facial nerve paralysis caused by trauma recover after 1 to 10 days of treatment, but some animals may require several months before resolution is observed. Occasionally the nerve deficits are permanent. In chronic cases, food should be removed from the cheek pouches twice daily, and the tongue and fauces should be routinely examined for ulcers. If present, oral ulcers should be treated by flushing the mouth.

35.90 TREATMENT OF PERIPHERAL NERVE DISEASES

Medical management of peripheral nerve injuries consists of reducing inflammation in the nerves, relieving musculoskeletal pain, preventing secondary medical complications (e.g., mastitis, fractures, joint/ligament tears), and preventing malnutrition and dehydration. Medical treatment for reduction of neurologic inflammation should be instituted as soon as possible after the injury.[2472] Dexamethasone (0.05 mg/kg IV daily for the first 3 to 5 days after injury) may be beneficial. Plasma concentrations of calcium, magnesium, and potassium should be measured repeatedly, because low levels of these electrolytes may aggravate the muscular weakness, increase the animal's struggling, and enhance the severity of the musculoskeletal lesions. Calcium gluconate can be given empirically to down cows (500 mL SC daily), as may potassium chloride (100 g in 20 L of water given daily by stomach tube). Concomitant administration of phenylbutazone by intravenous injection and application of cold water or ice packs to the affected part also may be beneficial during the first 24 hours after injury. Appendicular pain may be controlled by administration of nonsteroidal antiinflammatory drugs (e.g., banamine, phenylbutazone, or salicylic acid) and/or narcotic analgesics, including Demerol (1 to 2 mg/kg IV) or morphine (0.07 to 0.14 mg/kg IV).

Affected patients should be placed in a dry soil stall that has been deeply bedded. Concrete-floored stalls should be avoided because the poor footing may promote an accidental fall that worsens the musculoskeletal lesions. Recumbent animals should be turned six to eight times daily to prevent decubital ulcers and pressure myopathy. Support of some patients in slings may be useful for minimizing decubitus and maintaining strength in the opposite limbs. Goats tolerate dog slings well, but care must be used when lifting cattle in a hip sling because the device may cause severe contusions of the muscles at the point or attachment to the tuber coxae. The hip sling should not be used repeatedly to support cattle that fail to support weight when lifted. Abduction of the rear limbs may be prevented in cattle by application of a hobble around the metatarsus. The distance between the legs should be approximately 35.6 to 50.8 cm (14 to 20 inches) when the legs are tied together and held abducted. It is important to apply the hobbles with a nontightening bowline knot to prevent strangulation of the foot.

The prognosis is poor for animals with neurologic dysfunctions lasting longer than 2 weeks.

35.91 DOWN COWS (ALERT DOWNERS)

JOHN A. ANGELOS

BRADFORD P. SMITH

Down cows, downer cows, or downers are cattle that are recumbent and cannot stand; those that can maintain sternal recumbency while continuing to eat and drink are classified as “alert downers.” Common underlying causes of recumbency in cattle include mastitis (especially coliform mastitis), metritis, musculoskeletal disease (primary musculoskeletal injuries, including fractures and torn muscles/tendons), neuropathies secondary to pelvic trauma (calving paralysis or “obturator” paralysis), spinal cord compression (secondary to lymphosarcoma), and metabolic disease (hypocalcemia, hypokalemia, hypophosphatemia, hypomagnesemia).[2478] Following the initial episode of recumbency, secondary muscle and nerve injury caused by extended periods of recumbency on a firm surface may further exacerbate the recumbency. Heavy cattle down on concrete are particularly susceptible to pressure ischemia of the muscles and nerves and to muscle and ligament tearing secondarily to repeated struggling and slipping. The severity of pressure damage depends on regional anatomic factors and the duration of compression.

Identifying underlying causes for recumbency in downer cattle represents a diagnostic challenge for the practitioner. Assessing prognosis and determining reversibility of the underlying condition are necessary for practitioners to assist producers in making treatment decisions, as well as to conform to laws and abide by ethical norms surrounding humane handling of down animals. The American Veterinary Medical Association (AVMA) Position Statement on Disabled Livestock indicates that nonambulatory animals on the farm are not to be dragged; in cases of irreversible recumbency or extreme distress to the animal, the animal should be humanely euthanized or humanely slaughtered on the farm (where allowed by state law).[2479] Although current U.S. law prohibits dragging of nonambulatory animals under any circumstances,[2480] legislation that would require humane euthanasia of any recumbent animal at a place of commerce has also been proposed (Downed Animal Protection Act).[2481]

Laboratory testing for metabolic causes of recumbency would be ideal in all circumstances, but this is often not feasible or possible. As such, many downer cattle are treated empirically for suspected metabolic abnormalities, and response to treatment aids in establishing the diagnosis. Periparturient downer cows should be treated for hypocalcemia with one or more doses of calcium. Animals that become more alert but that are not standing after one or two doses of calcium are classified as alert downer cows. It is reported that 3.8% to 28.2% of all milk fever cases become alert downers,[2474–2476,2482] with a mortality rate of 20% to 67%.[2474–2477] The incidence of downers (24 hours or longer) was 21.4 cases per 1000 cow-years in Minnesota dairy herds, with a 33% recovery rate.[2483] Fifty-eight percent of downers occurred within a day of calving, and 97% occurred within the first 100 days after calving.[2483]

1109
1110

Because the pressure damage done to muscles and nerves is aggravated by recumbency, it is desirable to have the animal on soft bedding (e.g., sand,[2484] grass) and to have the animal stand as soon as possible. Eight of 16 normal cows anesthetized for 6 to 12 hours in sternal recumbency with the right hindlimb under the body were unable to stand on recovery and became alert downers.[2485] Those that could stand exhibited swelling and stiffness and peroneal nerve deficits and paresis in the right hindlimb.[2485] These signs are typically seen in cows that have been

recumbent for several hours on a hard surface. As pressure applied to a nerve increases, nerve conduction is impaired and eventually lost.[2486]

Serum creatine kinase (CK) values in experimental downer cows increased, starting at 12 hours and continuing up for the first 48 hours, and then decreased, even though the cow remained down.[2485] The CK values at 12 and 24 hours did not differ statistically for the cows that could rise after anesthesia and the downers. After 48 hours and 96 hours, the downers had higher mean CK values than the ambulatory group, but there was a great range in values.[2485] In another study of downers, aspartate transaminase (AST) levels were greatly elevated on days 4 to 7, even after CK levels fell.[2487] The clinical difference between cows that recovered and those that remained downers was attributed to damage to the sciatic nerve or its branches, particularly the peroneal nerve.[2485] Peroneal nerve damage results in knuckling over at the fetlock. Serum levels of creatine phosphokinase, AST, and lactate dehydrogenase have been examined to determine whether these indices of muscle damage can predict recovery of recumbent dairy cattle. Of the three enzymes, AST has been shown to be most useful in predicting nonrecovery. Dairy cattle with an AST level greater than 171 U/L are 80% more likely not to recover than a dairy cow with an AST level less than 171 U/L.[2488]

Devices that aid and promote standing traditionally include hip lifters (hip clamp), slings, and inflatable bags. Although these devices help less severely affected animals to stand temporarily, they do not allow the animal to stand comfortably for hours and may even cause further trauma in animals that struggle. For these reasons, the use of water flotation has been explored as a tool in the management of downer cows. Rasmussen[2489] first reported on the use of a warm-water flotation system in Denmark in 1982. Commercial flotation systems practical for cows* are marketed in the United States.

For flotation therapy to allow the best chances for recovery, the animal should first be examined to determine that it is a good candidate for flotation, by ruling out fractures, severe spinal cord compression, and severe systemic illness. Identifying and correcting electrolyte disturbances (e.g., hypocalcemia, hypophosphatemia, hypomagnesemia, hypokalemia) are required for successful application of flotation therapy. Once metabolic or systemic illnesses have been addressed and the cow is considered strong enough to stand once supported by water, the cow is placed in the flotation tank as follows: (1) the water tank is positioned near the down cow; (2) the wheels and tongue are detached, and both ends of the tank are removed; (3) a mat is pulled from the tub to a position beside the cow, and the down cow is rolled or slid onto the mat; (4) the mat is winched or otherwise pulled into the tub, and the ends of the tub are put in place; they seal with rubber gaskets and large turnbuckles; and (5) the cow's head is held up a few inches by a rope halter, and a hose is inserted into the tub, which is filled with water as quickly as possible; the water temperature should be 37.7° C to 38.7° C (100° F to 102° F). Cows in lateral recumbency on the mat become sternal when 12 to 24 inches of water fills the tub and usually attempt to stand beginning when the tub is one-half to two-thirds full. If no hot water is available near the cow, or if the tub is not next to dirt or grass suitable for the cow to exit on, the wheels can be put back on and the cow easily trailered to a better location. In addition, it is helpful to have an assistant support the tail or have a means to pull the tail once the cow attempts to rise. This helps the cow maintain a sternal position during early efforts at struggling before the cow is actually standing. Before floatation of lactating cattle at the University of California, Davis, cows are milked and teat ends sealed with a rubber teat sealant; this is removed once the cow is removed from the tank before milking. The sealant is reapplied after milking in preparation for the next flotation.

Once the cow is standing in warm water, it is possible to determine which limb or limbs are paretic or painful by observing which limbs the cow is using to support weight. Most cows calm down and relax in a standing position within 5 minutes. Most will eat hay, and even first calf heifers that have not been handled much seem to be remarkably calmed by the warm water. Unlike horses, cattle do not panic or attempt to jump out. The cow can be

left in the water for 12-24 hours. If the water temperature drops below 35° C (95° F), some water should be released from the discharge valve and replaced with hot water; this is especially recommended in cold weather. When the decision is made to remove the cow from the tub, the water is drained, and the end of the tub facing the dirt, sand, or grass is opened. The cow is encouraged to exit *slowly* into a pen with good footing. Some cows fall as the water is let out, and others collapse once they try to walk. By observing how a cow is ambulating on exit, it is possible to determine whether hobbles should be placed onto the cow before the next flotation. If cows are considered at risk for splaying out while exiting the tank, it is recommended to apply hobbles before placing the cow in the tank.

Careful observation as the cow moves can be very helpful in trying to locate anatomic or functional problems. The animal that collapses can be pulled out on the mat and left on suitable bedding, dirt, sand, or grass until refloated after a period of rest. Advanced planning on location is important for successful use of flotation therapy. Cows that can walk out into a pen may or may not be able to stand by the next day and may need to be refloated. Cows may need to be floated for up to 10 consecutive days before they can arise by themselves. If cases are carefully selected to rule out fractures, severe traumatic stifle injuries, septic arthritis, and spinal cord compression, a recuperative success rate of 46% to 90% can be expected.[2489,2490]

1111

Flotation is most effective if applied early, before a downer cow develops serious myopathy and neuropathy. Studies have shown that water flotation is practical and effective, even when cattle have been down for 24 hours or longer.[2489] The sooner a postparturient alert downer cow can be floated after onset of recumbency, the shorter the time to stand. In one study of postparturient alert downer cattle treated with flotation therapy, the mean time to stand was shorter for cattle floated within 1 day of going down (mean, 2.8 days to stand) than for cattle floated after being down for 2 or more days (mean, 5.3 days to stand).[2490]
